ACKNOWLEDGEMENTS

The author wishes to express his indebtedness to the chairman of his supervisory committee, Dr. A. W. Westerberg, Associate Professor of Chemical Engineering, for suggesting the research topic and for providing the necessary guidance. The author also wishes to thank the members of the supervisory committee: Dr. F. P. May, Professor of Chemical Engineering, Dr. R. G. Selfridge, Professor of Mathematics and Director of the Computing Center, and Dr. F. D. Vickers, Associate Professor of Computer and Information Sciences.

Thanks also are extended to the National Science Foundation, which provided financial support through grant GK-18633. In addition to providing the funds for my research assistantship, this grant defrayed the extensive computer expenses incurred during the debugging of the 135 subprograms constituting the GENDER System.

Without this assistance and support, the development of GENDER would not have been possible.

AUTOMATIC COMPUTER GENERATION OF SOLUTION PROCEDURES TO LARGE SETS OF NONLINEAR SIMULTANEOUS EQUATIONS VIA GENDER

By

James Richard Cunningham

December, 1972

Chairman: Arthur W. Westerberg
Major Department: Chemical Engineering

Fundamentally, chemical process plant design is the solution of a large set of nonlinear simultaneous equations. For large and complex equation sets, it is frequently not possible for the design engineer to determine readily how the solution should proceed. Algorithms have been developed which analyze equation sets with respect to solution procedure. The algorithms do not generally attempt to solve the equation set, but merely provide the directions for solving to the design engineer. While computer implementation of certain algorithms analyzing equation sets has been accomplished, little emphasis seems to have been placed on the implementation of a complete analysis system integrating a number of algorithms. This dissertation presents an automatic and machine-independent system permitting the design engineer to direct solution procedure generation and execution via selections from a spectrum of analysis algorithms.

GENDER is the acronym for General Engineering Design Routines. The primary objective of GENDER is the development of a complete solution procedure. To be complete, a solution procedure must reflect (1) decision variable selection, (2) output set assignment, (3) tear variable selection

and (4) precedence ordering. These attributes are provided to a solution procedure by GENDER through a minimum tear analysis strategy. While only the minimum tear strategy has been furnished with the first version of GENDER, the GENDER System has been designed to readily accept additional analysis algorithms, expanding the analysis strategy repertoire.

The design engineer, having generated a solution procedure for an equation set, may perform the translation of the solution procedure into FORTRAN for execution. However, an interpreter capable of direct execution of a solution procedure is provided in GENDER. The interpretation capability, while sparing the engineer from the drudgery of translation, has a somewhat more noble purpose. If the design problem involves constrained optimization, the solution procedure will be subjected to a series of revisions as additions or deletions to the set of binding constraints are required. The optimization-solution procedure generation-execution cycle is potentially faster for interpretation than for FORTRAN execution owing to the elimination of the translation and compilation steps.

GENDER depends extensively upon list processing techniques. In fact, the solution procedure has been implemented as a list. In the list format, the revisions and rearrangements associated with an analysis strategy may be conveniently performed on a solution procedure. The application of list processing techniques is not restricted to the solution procedure alone, but permeates the GENDER System. Linked data structures of note include a paged storage system (REMOTE) and the sparse incidence matrix. The former is notable for compatability with mass memory and the latter for memory conservation (on machines lacking virtual memory).

CHAPTER I

INTRODUCTION

The objective of process design is the determination of equipment specifications and operating conditions which will meet certain production goals developed by management. Process design problems are not particularly amenable to solution. The equations quantitatively describing the equipment characteristics may be highly nonlinear, a situation further confounded by the presence of recycle streams. The recycle stream is necessary to economic operation, but it imparts a cyclic character to the design calculations just as it imparts a cyclic character to the process flow. To these complexities of process design, yet another must be added. Processing plants are frequently complex entities, consisting of many individual processing units connected by a maze of piping. This is particularly true if the process engineer intends to extend the scope of the plant model to include not just the major features of the process, but all unit operations. That is, the mathematical model is to resemble the processing plant as closely as possible.

The availability of large, powerful computers has caused process engineers to revise the design procedure. Prior to his introduction to computers, the engineer was forced to simplify the process model to facilitate the completion of hand calculations in a reasonable amount of time. While short-cut techniques were developed for some unit operations, the "assumption" reigned as the arme supreme. Unlike the human brain,

the digital computer is well suited to complex and repetitious calculations. The engineer could now expect solutions for large and complex process models without the uncertainties of simplification.

The new exactness permitted to the process engineer by the digital computer proved to be something less than a complete blessing. The programs developed by the engineer from the mathematical models all too frequently either failed to converge, giving no answer, or generated unreasonable answers. Research, both industrial and academic, determined that the computational difficulties were characteristic of particular formulations of a model. Further, certain formulations of a model may require more information to initiate cyclic calculations than other formulations. What had developed at this point was a new field of endeavor for process engineers: the study of process models. This study begins where the traditional concept of mathematical modeling ends.

The result of mathematical modeling is the development of an equation set descriptive of, for instance, a unit operation. This set of equations is not unique. That is, the algebraic rearrangement of one model produces another equivalent model. It is this rearrangement and its effects which have captured the attention of the process engineer. The result has been a variety of algorithms for selecting a particular model formulation.

The algorithms are rather specific in character, dealing with only a particular aspect of a process model. Algorithms have been developed for selecting the output variables for a set of equations, for selecting the variables for which value estimates are required to initiate cyclic calculations and for ordering the equations so that the calculation of each variable value will depend only upon variable values already calculated. These operations are respectively known as output set

assignment, tear variable selection and precedence ordering. The process engineer employs selected algorithms sequentially to convert the original model he formulated into an equation set amenable to computer solution. The particular selection of algorithms may be referred to as an analysis strategy. The strategy is largely dictated by the objectives of the design engineer, such as a minimum tear solution or a rapidly converging solution. Unfortunately, the execution of an analysis strategy must be primarily manual. Only a few algorithms have been programmed, all of which are machine dependent and isolated from other analysis capabilities.

The next step in this evolutionary development of process design would seem to be totally automatic process model analysis. The notion of automatic design is not original to this work (Kevorkian and Snoek, 1972; Soylemez, 1971; Mah and Rafal, 1971), but has been attempted previously. It is the limitations of other automatic design systems which have encouraged the present effort, the General Engineering Design Routines (GENDER) System. GENDER does not restrict the design engineer to a single analysis strategy by virtue of a library of analysis algorithms. Further, the inclusion of additional algorithms has been made relatively easy. While it is possible to convert the product of an analysis strategy, which we shall call a solution procedure, into FORTRAN code for execution, the GENDER System provides the capability of directly interpreting the solution procedure to produce a solution to the design problem. As a feature designed to permit compact problem representation, GENDER can accept indexed variables and equations. Finally, the GENDER System affords the design engineer with a problem solving medium permitting the convenient modification of the original design problem during the execution of the analysis strategy and/or interpretation of the solution procedure. This feature is essential to constrained

optimization where fluidity in the inclusion and exclusion of constraints is an absolute necessity. While many of these features have appeared in previous attempts at automatic design packages, they have to date not all appeared in a single automatic design system.

CHAPTER II

OVERVIEW OF THE GENERAL ENGINEERING DESIGN ROUTINES SYSTEM

The heart of the GENDER System is the solution procedure and is essentially the set of instructions for solving a set of simultaneous equations. In order to make possible direct machine interpretation of the solution, the solution procedure must be explicit and complete. The purpose of this chapter is to introduce the concept of the solution procedure, its terminology and its relation to the GENDER System.

In Chapter I and in the preceeding paragraph the term equation was used for a model constituent. To be more precise, the model constituents are actually equations and solved equations. That is, the model is composed of algebraic relations between variables and constants, but having the form

$$f(x,y,z,\ldots) = 0$$

rather than the solved equation form

$$x = F(y,z,\ldots)$$

In the solved equation form, the x is called the output variable. An equation may be transformed into a solved equation by selecting a variable to be the output and performing the algebraic rearrangement necessary to place this variable alone on the left-hand side of the equality.

Certain of the equations defining a processing plant may be constraints. Normally one thinks of constraints as inequalities. However, inequalities are readily converted to equalities via the intro-

duction of slack variables. GENDER, at least in its current version, is prepared to manipulate equality constraints only. Being identical to the equations describing the process, the constraints could be grouped with them without differentiation. However, during constrained optimization the set of active constraints varies in numbers and composition. To permit the free inclusion (exclusion) of constraints into (from) a problem, constraints are regarded as distinct model constituents and are carefully differentiated from all other model components.

Normally an equation is permitted but a single output variable, with one exception. The external routine (ER) is a special model constituent which may possesses more than one output variable. In essence, the ER is a subprogram for determining values to output variables given the values of the input variables. An ER may be encoded in any acceptable programming language.

To facilitate the incorporation of existing subprograms in a plant model, a mechanism for indicating prechosen output variables is essential. The mechanism selected for GENDER is a weighting scheme with an integer scale of 0 to 9. Each variable in each equation and ER is assigned a weight in the 0 to 9 range. This weight is the cost of assignment as an output variable. Thus, for an existing subprogram, the output variables are all weighted at 0 while the input variables are all weighted at 9. This weighting scheme allows the design engineer to indicate to GENDER his preferences with respect to output set assignment. For instance, similarity of a new model with one or more previous models may suggest at least a partial output assignment. The weighting mechanism allows the engineer to guide GENDER in performing the initial output assignment and may reduce execution time depending on the ultimate

degree of similarity between the solution procedures for the models.

In addition to output set selection, analysis of the equation set must also order the equations and, if possible, subdivide the functions into smaller groups. Initially, the plant model is treated as a single large group of equations. The decomposition of the large problem into a multitude of smaller problems is obviously advantageous. Equations which are acyclic in character may be grouped, although the equation grouping normally reflects the presence of a cyclic character. It is permitted by GENDER to have groups as members of groups. Thus, we may have, for example, a cyclic group appearing as a constituent of another cyclic group, or even as a constituent of an acyclic group.

Once tear variable selection has rendered all cyclic groups apparently acyclic (by ignoring all occurrences of the tear variables except in the equations where they are the output), it is possible to order all members of groups and to order all of the groups so that the information flow is strictly forward. That is to say, the value of a variable is never required as the input to a equation before it has been calculated as the output of a previous equation. This then is the concept of precedence ordering.

The solution procedure must reflect the output set assignment, grouping, tear variable selection and precedence ordering. The solution procedure must also indicate decision variable selection, the decision variables being the unassigned variables following output set selection. Numerous strategies exist for acquiring these ingredients to the solution procedure, but for completeness all must explicitly appear.

The solution procedure is called the GENDER list. The GENDER list consists of group, each group possessing a body of equations, ER's or groups. Each equation and ER appears once somewhere on the GENDER list.

Its position on the GENDER list is dictated by precedence ordering. Space is reserved with each equation and ER to indicate the selected output variables. Similarly space is reserved for the recording of the decision and tear variables associated with each group. The completed solution procedure will generally be evolved from a skeletal, random listing of the equations in a single group called the crude GENDER list.

The completed solution procedure contains all of the instructions for solving the equation set, but is as yet not amenable to interpretation. The conversion operation transforms equations into solved equations via algebraic arrangement. In lieu of destroying the original equation set, the converter operates on a copy of the equations. This feature of GENDER preserves the original model should reanalysis of all or a portion of the solution procedure be required. This eventuality might, for instance, be realized if convergence difficulties of a cyclic group are encountered. Once subjected to conversion, the solution procedure is transformed into an ordered and grouped list of solved equations ready for numerical evaluation.

The GENDER System is divided into five major program levels as shown in Figure 1. The program packages COAST (level 1), REMOTE (level 2), SIMPAC and NETPAC (level 3) are discussed in Chapter III. These packages provide the capacity to manipulate certain data structures essential to GENDER. Chapter IV introduces the data base SECEDE and provides greater detail on the GENDER list. The algorithms available for problem analysis are discussed in Chapter V. Level 4 of GENDER is devoted entirely to the analysis algorithms. The highest current GENDER level is level 5. On this level is found the input/output

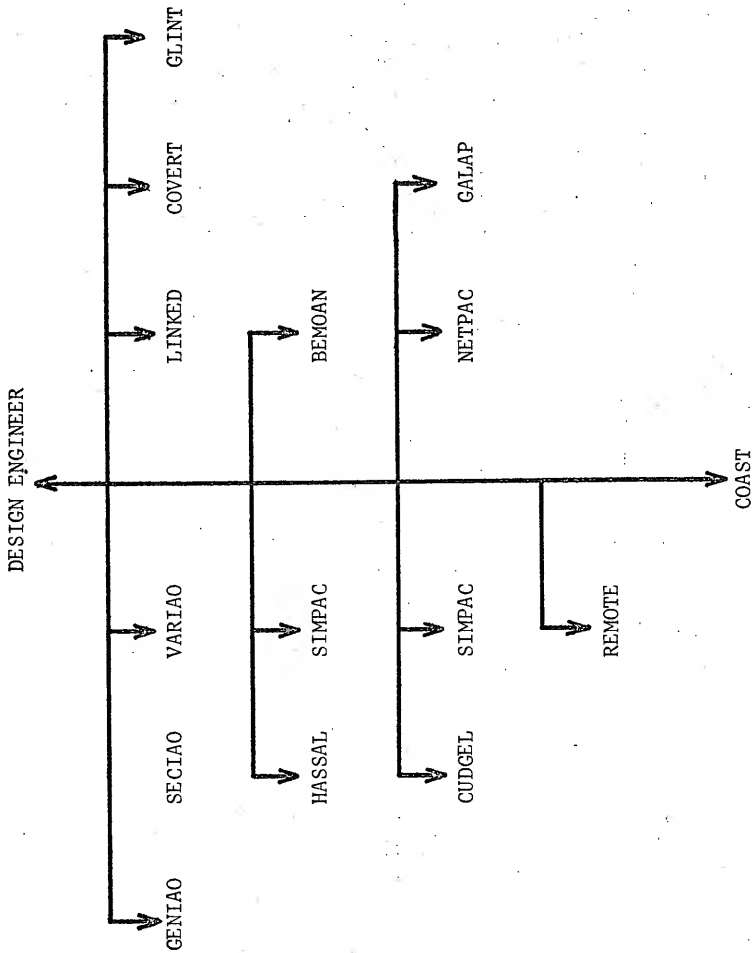

Figure 1. GENDER Architecture.

facilities and the programs relative to interpretation of the GENDER list. The description of the input/output facilities has been incorporated into Chapter IV. The notion of GENDER list interpretation is treated in Chapter VI. Chapter VII is a brief user's guide to the GENDER System. In this chapter the expansion of the repertoire of analysis algorithms is discussed, as well as the employment of GENDER as a design tool. Illustrative problems are presented in Chapter VIII. This work is concluded in Chapter IX with some remarks on the limitations and possible future of GENDER.

Particularly in the next four chapters, some sections are extremely detailed. In addition to being difficult to read, they are likely only of benefit to readers contemplating algorithmic additions or modifications to the GENDER System. For this reason, these sections are identified by an * in the section number and may be omitted by readers not requiring the implementation details of GENDER.

CHAPTER III

DATA MANIPULATION AND STORAGE

III.1. Data Handling

The algorithms for solution procedure development suggest certain data structures. Effective implementation of the algorithms requires the availability of these data structures. Unfortunately, the data structures require vast quantities of on-line memory. A large scale problem would, by virtue of the data structures developed during problem analysis, very quickly reach the bounds of on-line memory. Fortunately, not all of the data structures need exist at one time, making feasible the sharing of memory. A priori, the memory required by each phase of problem solving is unknown. Thus, the simple partitioning of memory is an infeasible sharing policy.

Two basic and complementary data storage mediums have been provided: lists and files. The list permits complex data structures which may be readily rearranged, expanded or contracted. The penalty for this flexibility is high access times. Reaching a particular location may be accomplished only by stepping through all preceding list locations. Conversely, the file allows rapid random access of any location. Files are, however, restricted to a strictly sequential structure. Memory sharing is accomplished by a dynamic memory allocation procedure. For readers not familiar with list processing, Knuth (1968) provides a complete discussion of list processing principles and structures, including memory allocation.

III.1.a. Lists

Figure 2 is an illustration of three possible list structures. As

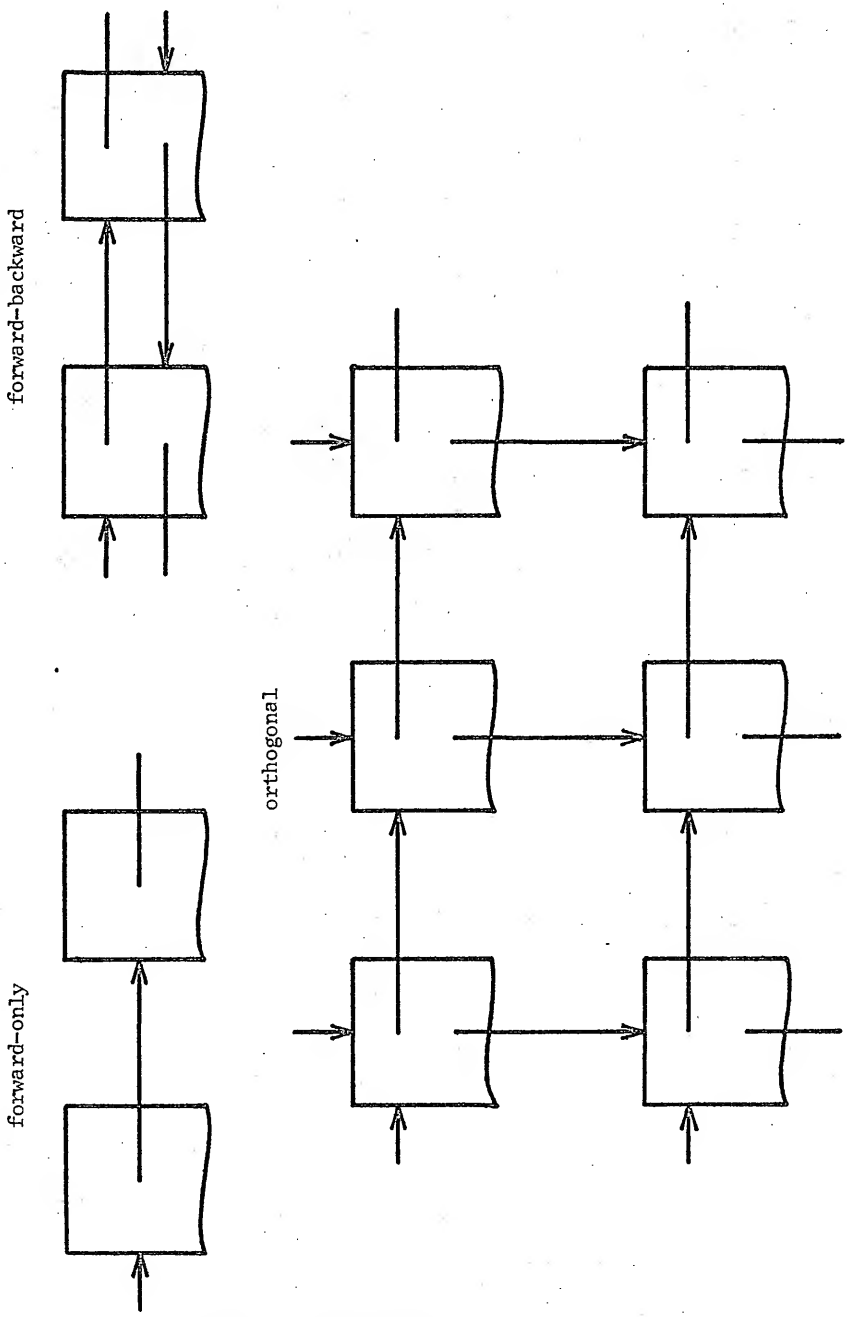

Figure 2. Typical List Structures.

indicated pictorially in Figure 2, the structure of a list is relatively arbitrary. The arrows in Figure 2 represent the connection between list entries and are called links. Thus one data item (at least) in a list entry is a pointer to an adjacent entry on the list. This flexibility has not been restricted to structure alone. Each entry on a list possesses the attributes of size, quantity of data and organization of the data within the list entry. All of these attributes are also arbitrary.

The structure of a list, while arbitrary, is specified by the programs which generate and manipulate the list. That is, the degrees of freedom permitted in the selection of a list structure are consumed by the programmer of a list processing application. Since one of the objectives was machine independence, and since word size and memory size vary from machine to machine, it seemed necessary to segregate the organization of data within list entries from the tailoring of list structures to meet strictly programming requirements. This has been accomplished by designing the list processor to accept the data organization parameters as data prepared and supplied by the user. These parameters are further discussed in Chapter VII.

The utility of a list processor lies mainly in the usefulness of its operations. We shall call the subprograms providing these operations "verbs." Verbs have been provided for obtaining and releasing list entries and for making and breaking the links between list entries. These verbs form the nucleus of the structure manipulation power of the list processor. Another set of verbs provides the capability for transferring information to or from a list entry. Of great utility is the ability to search a list for the occurrence of a particular set of data values. A verb providing this service is also included in the list processor.

III.1.b. Files

Figure 3 is an illustration of a typical hierarchical file. The arbitrariness of structure present in lists has, for files, been reduced to the specification of the number of levels in the hierarchy. Rapid access to randomly selected entries at any level is the incentive for the sacrifice of arbitrariness in structure. Owing to the sequential storage of file entries in on-line memory, large contiguous blocks of memory allocation may be required. It is, therefore, vital that the file system utilize core effectively. However, the sequential nature of the file entries makes possible the transfer of file data to mass memory devices. This enables the release of on-line memory normally occupied by files during problem solution phases not relying on the file data. Further, even when file data is required, it is possible to retrieve only portions of a file.

A file entry is essentially the same as a list entry, except that the explicit specification of links, as in the list entry, is absent. The organization of data within a file entry is accomplished identically as for a list entry. Thus, the file entry shares the same arbitrariness of data organization provided for the list entry.

Many fewer verbs need be provided for file manipulations than for lists since link manipulations are not required. In fact, three verbs are sufficient. One verb is required to provide a file entry and transfer data into it. A second verb provides the capability for retrieval of data from a file entry. Finally, the third verb permits the searching of a file for a particular set of data values.

III.1.c. Memory Allocation

The particular memory allocation strategy adopted for GENDER continues the theme of flexibility and arbitrariness. Each phase of

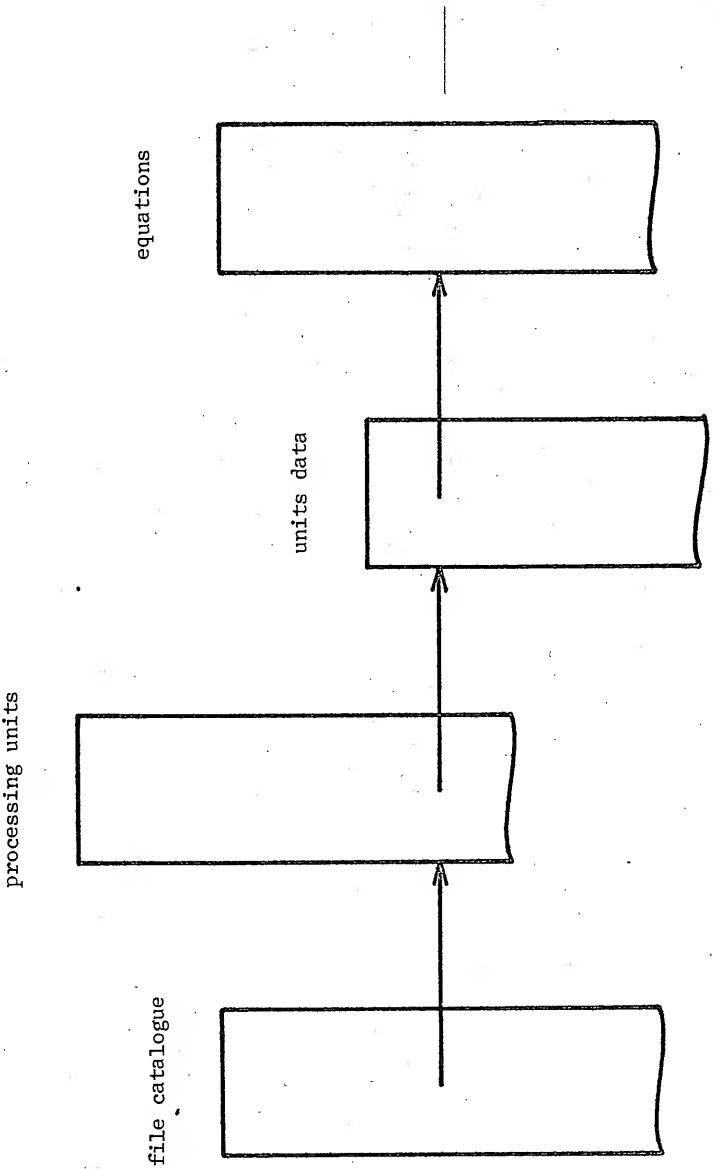

Figure 3. Typical Hierarchical File.

problem solving is allocated memory only as it is required. An accounting mechanism keeps track of the memory assigned to each phase. This mechanism permits the release of memory assigned to a particular phase once its task is complete. The released memory may then be reallocated to another phase of problem solving. The allocation, release and re-allocation capabilities give memory the fluid character essential to providing a time varying memory distribution in response to the time varying demands of the solution phases.

The dynamic allocation of memory provides an opportunity for fracturing memory into small isolated segments. This eventually would prevent the servicing of a request for a large continuous allocation of memory. Though procedures such as garbage collection have been proposed for reclaiming the isolated memory, these procedures have not been used for GENDER. The need for large blocks of memory has been avoided by designing the file system so as to utilize only reasonably sized continuous blocks of memory.

III.2. Special Data Structures

Networks - Since the algorithms for solution procedure development in many instances specify rearrangements of the solution procedure, a list structure was adopted. Hence, the solution procedure became known as the GENDER list. During the course of evaluation of the entries on the GENDER list via the interpreter, an anomaly may be encountered necessitating reanalysis of a portion of the GENDER list. In fact, all of the GENDER list from the anomaly to the list end is subject to reanalysis. Consider the following set of equations.

$$\begin{aligned} \underline{Y}(\underline{y},\underline{u}) &= \underline{0} \\ \underline{Z}(\underline{z},\underline{v}) &= \underline{0} \end{aligned} \tag{1}$$

If reanalysis of $\underline{Y}$ is required, $\underline{Z}$ would be subject to reanalysis,

although reanalysis of Z would result in no change. Instead of the list structure, suppose a structure is substituted in which each entry precedes only those entries that it influences. Then, Y and Z would appear on parallel paths since they are independent. This structure is a network, and was adopted for the solution procedure (which is still called the GENDER list).

Sparse Incidence Matrices (SIMs) - Incidence matrices provide a convenient and lucid medium to express the problem to which an algorithm is to be applied. In fact, many algorithms for solution procedure generation are most easily explained in terms of their effect on incidence matrices. This is to suggest that incidence matrices may be a natural and effective tool in the implementation of these algorithms. Unfortunately, matrices are relatively expensive in terms of memory requirements. This is particularly damaging in light of the intention to construct GENDER so as to be applicable to large scale problems. In chemical engineering, and perhaps in other disciplines as well, most equations contain only a small number of variables compared to the total number of variables in the problem. The average incidence for several chemical engineering applications examined was approximately three to four variables per equation. The majority of the incidence matrix elements are null. By considering the matrix elements to be list entries, and by disregarding all null elements, the use of incidence matrices is made possible without the disadvantage of excessive memory requirements. The elements form the orthogonal list structure shown previously in Figure 2. For example, if an equation contained only two variables, then the row would be composed of only two list entries. The columns represent variables so that each of the two row list entries are also members of the orthogonal column lists as well.

III.2.a. Networks

A network is an extension of the forward-backward list structure to permit each list entry more than a single forward and a single backward link. The capacity for parallelism is furnished by auxiliary lists called divergers. All list entries other than diverger entries are referred to as network nodes. Figure 4 depicts a node followed by three parallel nodes.

Networks have virtually all of the attributes associated with a forward-backward list structure. The arbitrariness of data organization within the nodes is somewhat restricted by the requirement that certain data entries be present as an integral part of the structure. Highly parallel structures may suffer with respect to access times as a result of large divergers.

The network verbs implemented are essentially concerned with the peculiarities of network linkages. The list processing verbs for data transfer serve equally well for nodes as for list entries. Subprograms are provided for the connection and for the separation of nodes. A complementary pair of function subprograms permits the extraction of linkage data, one for the forward link and one for the backward link. The policy of providing the capability for searching list structures is continued here for networks. Finally, a rather special verb is provided enabling an orderly, predictable tracing from node to node through a network. This verb, a function called NEXT, has proven to be of considerable utility.

III.2.b. Sparse Incidence Matrices

Sparse incidence matrices are actually a hybrid of the orthogonal list and of the file data structures. Figure 5 illustrates a sparse

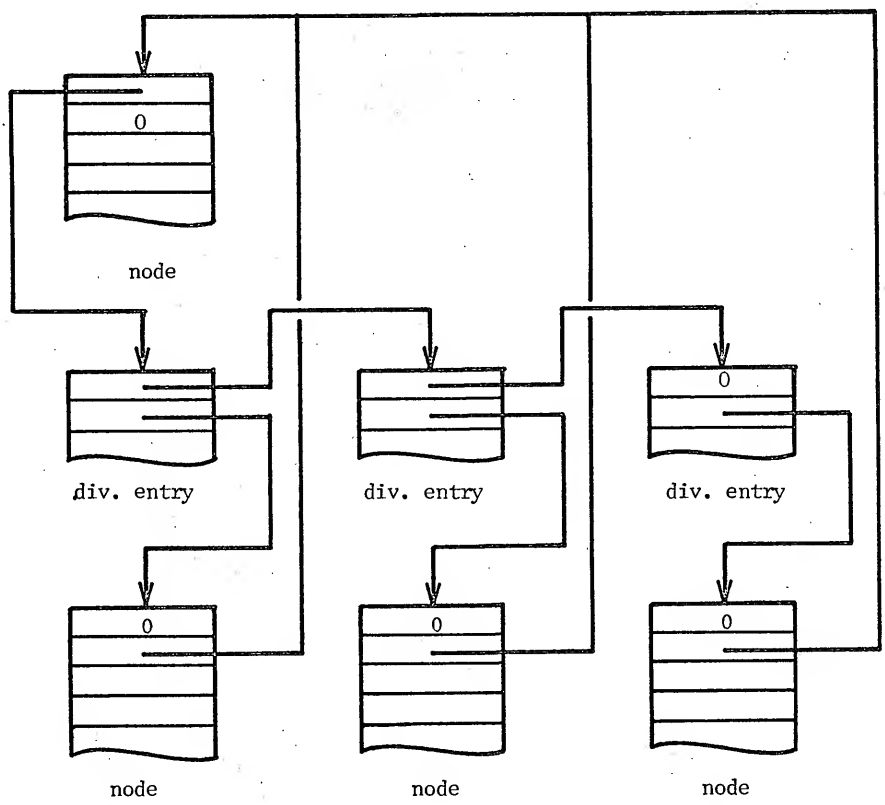

Figure 4. A Simple Network.

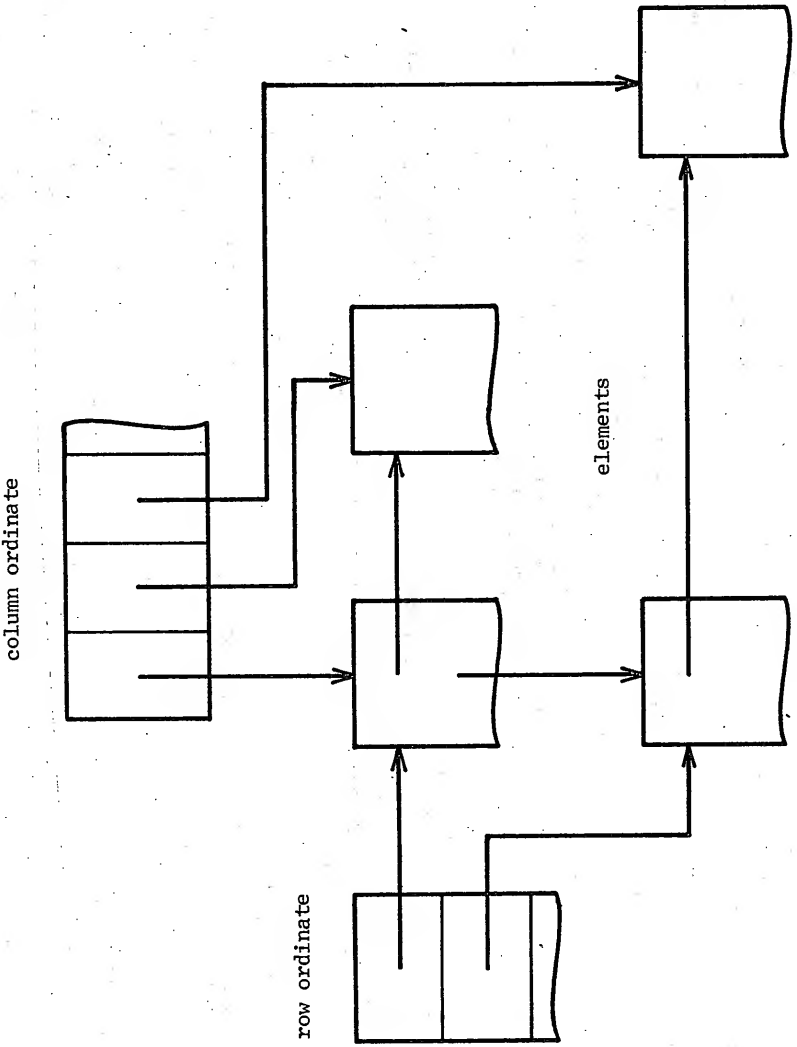

Figure 5. Sparse Incidence Matrix.

incidence matrix consisting of two equations and three variables. The files required for the sparse incidence matrix are termed ordinates. Each file entry contains a pointer to a row or column of the matrix. For simplicity, when reference is made in general to a row or column the term vector will be employed.

Even with the inclusion of the two ordinates, the memory conservation remains substantial. Consider a system of 1,000 equation in which 1,000 variables are incident. The resulting incidence matrix must contain no fewer than 1,000,000 words of memory if stored as a standard two dimension array. Allowing three words per non-null element (for the horizontal link, vertical link and data item), the elements of a typical sparse incidence matrix would consume only about 9,000 words. The ordinates and supporting data structures would require at most approximately 30,000 words. Thus, the memory savings afforded by the sparse incidence matrix exceeds 960,000 words over the simple two dimensional array. If the ability to pack information into list and file entries is utilized to its fullest extent, the size of the sparse incidence matrix may be reduced by as much as 50% depending upon the word length. The penalty for memory conservation is increased access time. A matrix vector may be accessed randomly and relatively quickly by virtue of the ordinates. Reaching a particular element list entry, however, can be accomplished only by tracing the selected vector from element to element until the desired element is accessed.

The nature of the subprograms provided for the manipulation of sparse incidence matrices are rather specific in character. Each subroutine is designed to fulfill the requirement by one or more of the algorithms for a certain sparse incidence matrix operation.

III.3. Implementation Details

The implementation of the data handling facilities discussed in Sections III.1 and III.2 has been partitioned into four program packages. COAST is the name given to the program set providing the core allocation and list processing capabilities. The subroutines furnishing the file manipulations constitute the REMOTE system. NETPAC and SIMPAC are respectively the network and the sparse incidence matrix program sets. Each of these packages are discussed in detail in the subsections to follow.

The remainder of Chapter III may be omitted by any reader not requiring a knowledge of the programming details. A knowledge of these details is not expected to be generally advantageous except to those readers planning additions to the algorithm library, alterations to an existing algorithm, or alterations to the GENDER facilities.

* III.3.a. COAST

To achieve machine independence, FORTRAN was selected as the programming medium. To provide the space required for the development of list structures, a COMMON declaration was employed to reserve a vector named ALLOC. The length of ALLOC is a user specified parameter. The position of a word of memory within ALLOC is referred to as the absolute address, or simply address, of that word. For example, the fifth ALLOC word has an address of five.

The memory allocation strategy adopted for GENDER is the buddy system. To reduce the administrative effort required in supervising the allocation of ALLOC to user programs, ALLOC is partitioned into multi-word segments. Segment size is also an adjustable parameter. To permit the allocation of space in sizes other than a single segment, consecutive segments may be combined to form buddies. In fact, two contiguous blocks of memory

of equal size may be combined to form a buddy. Requests for space are satisfied by supplying the smallest buddy satisfying the request. Should only a larger than necessary buddy be available, a request for a lesser amount of space may be satisfied by first fracturing (splitting into two parts) the larger buddy. All of the available buddies of each size are linked together forming an available space list for each buddy size. The operations necessary for memory management are provided by the subprograms C8COMB and C8GIVE.

In order to facilitate the release of ALLOC segments by user programs, an accounting system is necessary. The accounting device adopted is a mask. Each bit of the mask represents an ALLOC segment. A set bit in a user's mask indicates that the corresponding segment is assigned to that user. Each user program is assigned a user mask on its initial request for space. Figure 6 is an illustration of a user mask. A similar mask, established before allocation commences, is provided to record segments released by user programs. Whenever the buddy available space lists become sufficiently depleted that a request for core cannot be honored, then the space represented by the return mask is re-buddied and returned to the available space lists. This strategy eliminates execution of the costly re-buddying process unless it is absolutely necessary. CORN is the program furnished to permit the release of ALLOC segments by a user. The program LIST accomplishes the update of a user mask as memory segments are made available to a user program.

A user program requests space via a five word vector called a space utilization record (SPUR). The first word of the vector contains the address of the user mask. For the initial space request, this word must contain the integer zero. The second word will contain the pointer to

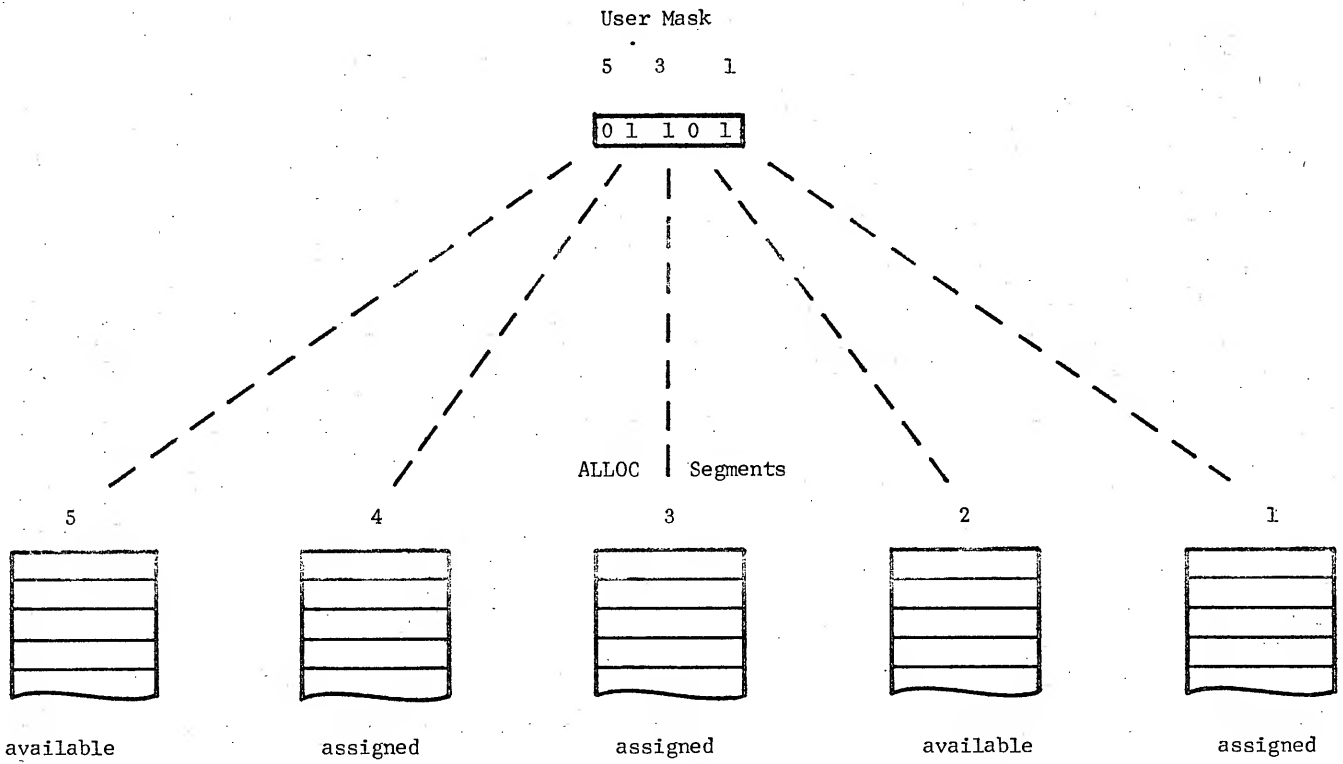

Figure 6. A User Mask.

the space provided during allocation. The third and fourth vector components are respectively the quantity and the size in words of the requested list entries. The list entries are manufactured from a buddy of the appropriate size and provided to the user program as an available space list. The last component of the SPUR indicates the list type, a subject to be considered later in this section. Several programs requiring ALLOC space may share a SPUR vector, thereby sharing the allocated core.

Information is contained within list entries in data fields. A data field consists of either all or a portion of a list entry word. Data fields consisting of only a few bits are usually referred to as flags. A data field appearing in one or more consecutive list entry words constitutes a data type. The collection of all data types associated with the entries of a particular list structure constitutes a list type. The quantitative specification of a data type requires four parameters. The first two delimit the bounds of the data type within a list entry. For example, if these parameters are valued at 1 and at 4, the data fields of this data type appear in words 1 through 4 of the list entry inclusively. The second pair of parameters delimits the bounds of the data field within a list entry word. The third word, called a shift, is the integer by which a list entry must be divided to place the first bit of the data field in bit position 1 of the dividend. For instance, if the data field begins in bit position 3, dividing by a shift of 4 will translate the field the required two positions. The last parameter is a field mask comprising set bits indicating the bit pattern of the data field. The field mask should be right justified to the first bit position of its single word. The collection of all sets of these four parameter vectors constitutes

the list entry definition (LEND) specifying the organization of data fields within the list entries of a list type. Thus, a LEND is required for each data type. COAST utilizes the subroutine COIN to accept the LEND's from a user as data. COIN is the only COAST routine requiring data.

In order to accomplish the transfer of information to or from the data fields within a list entry, the data fields involved in the transfer operation must be uniquely identified. It is to be permitted that a single transfer operation may involve many data fields from many different data types. Thus, the transfer operation requires two vectors, one reserved for the values of the data fields and a second to identify the data fields. The latter vector consists of three words per data type involved in the transfer, plus an additional word specifying the number of data types. Each three word set comprises a data type, the occurrence of the first field for transfer and the occurrence of the last field for transfer. For example, a three word set (4, 2, 7) indicates that the data type is 4, the first field transferred will be the second and the last field transferred will be the seventh. The transfer for data type 4 will consume six words of the value vector. All of the COAST verbs performing data transfer operations employ the vectors described here, except COPY. COPY performs the direct list entry to list entry transfer of information, and does not require a vector for value storage.

The first occurrence in a list entry of data type 1 was selected for the forward link. Similarly, the first occurrence of data type 2 is reserved for the backward link when backward links are required. Technically, links are simply data fields and may be manipulated as data fields using the data transfer subprograms. The convention adopted

regarding data types for links permits the creation of faster, more convenient verbs specific to link manipulations.

It is the nature of the forward-only list to prohibit the access to the predecessor of a list entry. The absence of the backward link makes necessary special handling of operations involving the removal of entries from a forward-only list. In particular, if the last entry is to be removed, it is not possible to set the forward link in its predecessor to zero since the address of the predecessor is unknown. In this situation, the last list entry becomes a private termination cell, PTC, (Cooper and Whitfield, 1962/3) and is fitted with a forward link of 1. Thus, a unity forward link is the identifying characteristic of a PTC. PTC's remain linked into the list but are not otherwise an active part of the list. If the list entry is to be removed from a forward-only list, the entry itself cannot be physically removed as its precursor in the list (which points to it) is not known. However, by copying the entire contents of the list entry following the one to be removed into the list entry to be removed, one has created the effect of removing the chosen entry. The list entry following is then deleted from the list and added to the user's available space list.

Table 1 presents a list of the COAST verbs which are the primary list processing subroutines. Omitted from Table 1 are those COAST programs which are not of direct utility to the programmer of a list processing application. Three verbs included in the table require further attention.

LOCATE, as its name implies, searches a list for the occurrence of a specified pattern of data field values. The data specification vector employed in data transfer operations provides LOCATE with the

TABLE 1

COAST Verbs

Nature	Name	Function
Initialization	COIN	Read in LEND's
Core management	CORN	Release core assigned to a user mask
	NEWCEL	Provide list entry from user available space list
	RETURN	Return list entry to user available space list
Link manipulation	BSTLNK	Set backward link
	FSTLNK	Set forward link
	LNKBWD	Get value of backward link
	LNKFWD	Get value of forward link
Data transfer	COPY	Transfer data from list entry to list entry
	FRMCEL	Extract a copy of data from list entry
	TOCELL	Store data in list entry
Link manipulation and data transfer	LOCATE	Search list for certain data
	POPUP	Perform FRMCEL and remove list entry(s)
	PUSH	Install new list entry and perform TOCELL

identification of the data fields to be inspected. LOCATE permits two modes of operation which are referred to by the descriptors "AND" and "OR". In the "AND" mode, LOCATE is directed to accept as a match the first list entry found to contain the specified data pattern in its entirety. The "OR" mode relaxes this requirement for matching somewhat. In the "OR" mode, the data pattern is partitioned according to data type. The partitions are compared individually to their respective data fields of a list entry. The search is successful when a list entry is encountered possessing the fields of a data type which match the corresponding data value partition. In either mode, the search may be specified to proceed in the forward direction, in the backward direction or specified to encompass the entire list (accessible from the specified starting point).

Like LOCATE, the verbs PUSH and POPUP involve both links and data, but unlike LOCATE result in alterations to the list structure. The PUSH operation is pictorially presented in Figures 7. Although the illustrations are based on a forward-backward list, PUSH operates essentially the same on forward-only lists with two exceptions. Owing to the absence of the backward link, the push-up mode and the insert-before mode cannot be performed per se. If the position of the data on the list is the important consideration and not the address of the particular list entry containing the data, then the insert-after mode and the push-down mode may be taken as the equivalent of the push up and insert before modes respectively. The verb POPUP is essentially the inverse of the verb PUSH. Figure 8 shows the POPUP operation in the forward direction. In the case of forward-backward lists, POPUP is symmetrical and will operate equally well in the backward

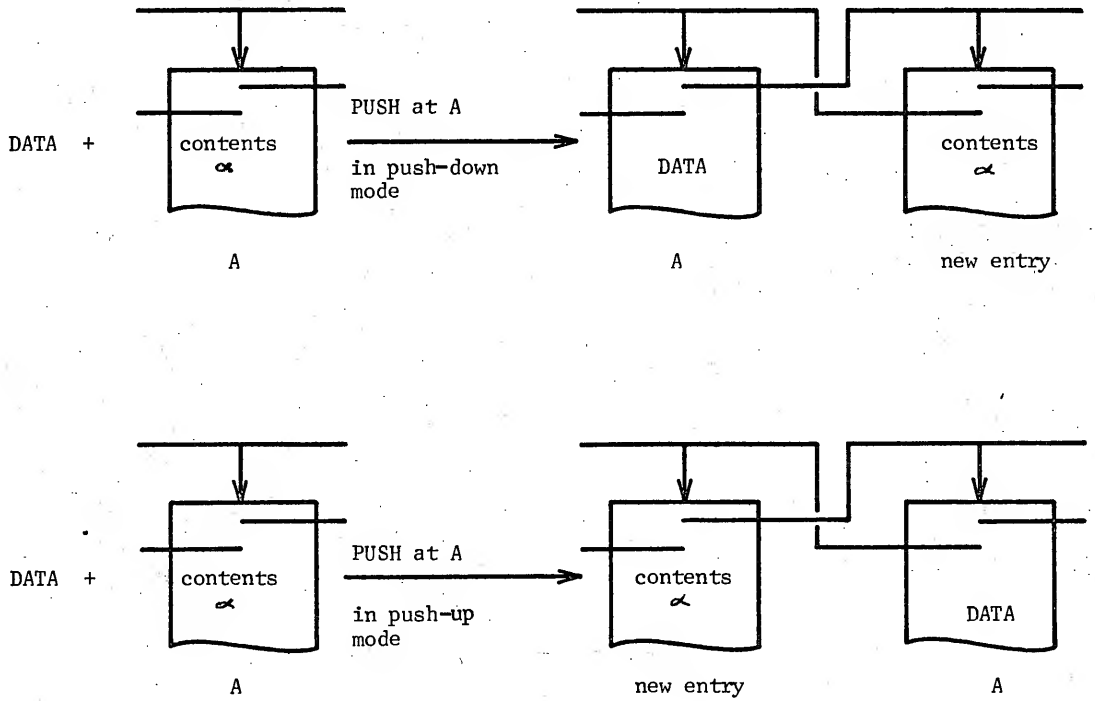

Figure 7. PUSH.

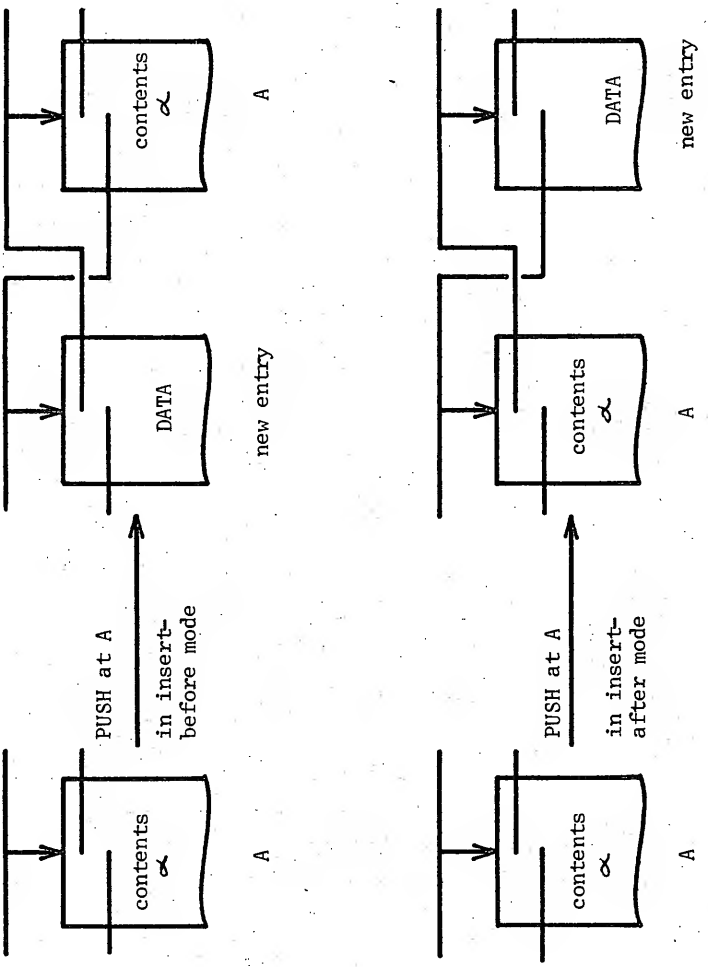

Figure 7.. PUSH (continued).

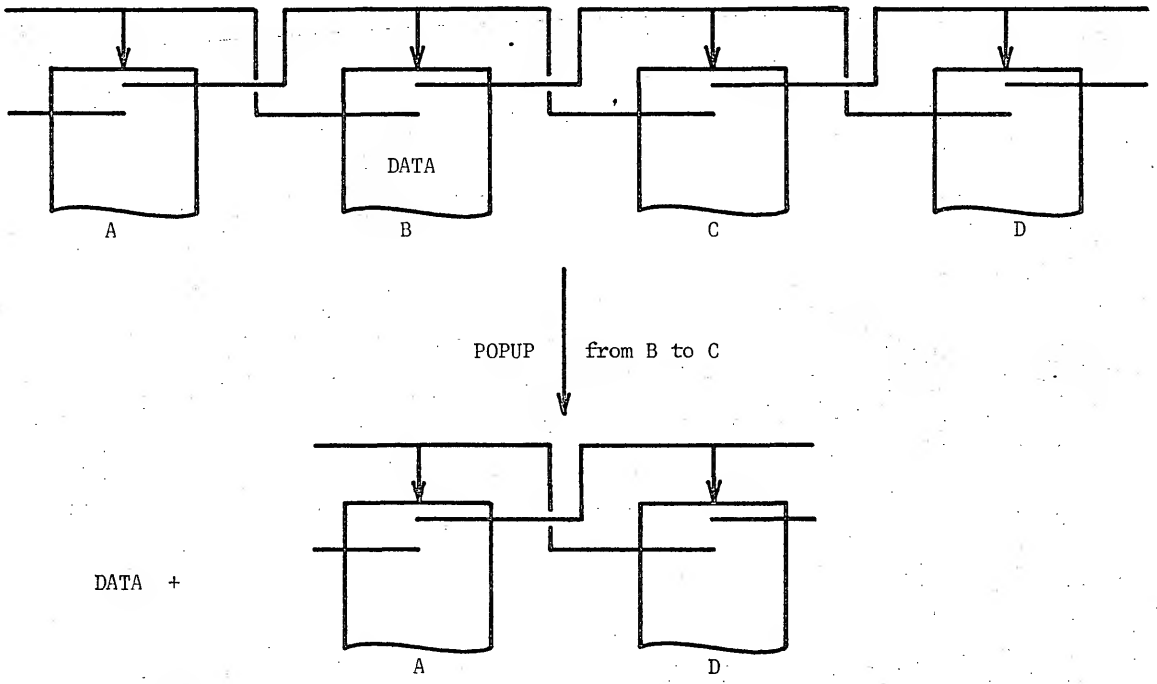

Figure 8. POPUP.

direction. Thus, if POPUP from C to B (according to the backward link) is specified, the entries from B through C in the forward sense will be transferred to the user available space list. The data source will be list entry C. In the example of Figure 8, if the operand C were replaced by 0, POPUP would remove from the list all entries from B to the end of the list. For a forward only list, B would of course become a PTC. Again, the symmetry of POPUP allows this mode of operation for forward-backward linked lists.

As stated at the beginning of this section, machine independence was a goal of the GENDER system design. Unfortunately, the logical operations "AND", "OR" and "exclusive OR" are required for the mask manipulation operations. These logical operations cannot be conveniently provided directly in FORTRAN, necessitating recourse to assembly language. These operations are basic machine instructions and required little effort to prepare for the IBM-360 or 370. This is expected to be true for all other machines as well.

* III.3.b. REMOTE

Avoidance of dependency of the hierarchical file storage system, REMOTE, on large continuous partitions of the ALLOC vector was a paramount consideration in the design of REMOTE. The design is to require file storage in smaller ALLOC partitions, which are somehow connected together to give the illusion of being contiguous. As a further constraint, the linkage mechanism must not seriously interfere with the intention to permit file storage and retrieval form mass memory.

Figure 9 shows the structure adopted for use by REMOTE. The catalogue consists of a forward-backward linked list of ALLOC segments (which could contain, say, 32 or 64 words each). The forward and

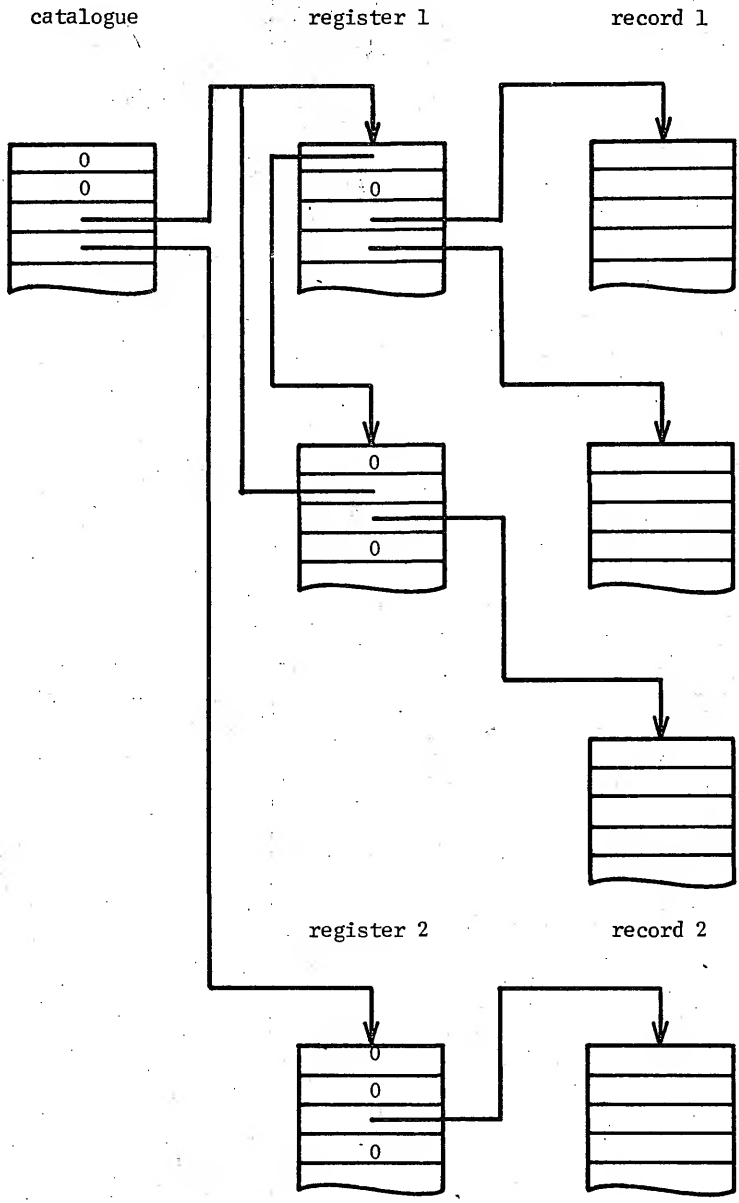

Figure 9. File Structure.

backward links are respectively the first and second words of each catalogue segment. All other catalogue segment words may contain the address of a register. A register is identical in structure to the catalogue. Each register segment word (excluding the first and second) may contain the address of a record segment. The set of all record segments referenced by a single register constitutes a record. It is customary, since a one-to-one correspondence exists between registers and records, to say that the catalogue refers to records.

It is in the record segments that the files are stored. Record segments may be any desired multiple of the ALLOC segment size. The size is specified via the SPUR vector introduced in the preceding section. The continuity of a record (or should we say apparent continuity) is achieved by virtue of its register. The absolute addresses of all record segments participating in file storage are kept in the register segments. Zero contents of a register segment word indicate that the corresponding record segment has not yet been requisitioned from ALLOC. A negative integer stored in a register segment word indicates that the contents of the corresponding record segment are currently resident on mass memory.

Let us briefly review the objectives and constraints noted in the first paragraph of this section before pursuing the features permitting the hierarchical character of file storage. The use of record segments certainly satisfies the stipulation of eliminating any dependence of the file system on large partitions of ALLOC. The registers provide the linkage mechanism for the record segments which is thus segregated from the records and interference with mass memory operations is therefore minimal. Further, the linkage mechanism seems to satisfy the requirement to provide rapid random access and gives the record

apparent continuity to the user. It is important to note, however, that these objectives were met without creating a support structure that would require a large amount of memory. For example, consider an ALLOC segment to be 32 words and a record segment to be 64 words. A catalogue segment and a register segment, a total of 64 words, can hold the addresses for up to 30 record segments or a total of 1920 record words. Thus, the support structure (catalogue and registers) only consumes slightly over 3% of the total memory allocated to a file storage application.

The responsibility for the hierarchical character of the file storage system belongs to the directory concept. Consider, if you will, a file consisting of single word file entries. Into each file entry place the address of a file. This then is the notion of a directory. It is a file which refers to subsequent files. One or more of these subsequent files may also be a directory giving rise to the hierarchical property. However, care must be exercised with respect to the addresses employed in the directory entries. If absolute addresses are used, the file system would become dependent upon the particular ALLOC buddies serving as record segments. This would seriously impair the use of mass memory. An addressing scheme independent of the absolute addresses of the record segments is required; a relative addressing scheme is used.

The relative address of a particular word in a record is simply the integer identifying its sequential position within the record. That is, the ninth word of a record has for its relative address the integer 9. (We shall adopt the convention that the word "address" appearing without the modifier relative will be taken to mean "absolute address.")

The absolute address is readily calculated from the relative address by using the register. If a record segment has 64 words in it then relative address 132 is in the third record segment, word 4. The absolute address of the third record segment is kept as the third entry in the register.

When preparing to add a new file to a record already containing one or more files, it is necessary to know where the last file ends. To this end, the first word of each record (the word in relative address 1) is reserved for the relative address of the first empty word in the record. It is also advantageous, when manipulating a particular file within a record, to know how many file entries constitute the file and how many words each file entry occupies. A special file entry appears as the first entry of each file containing these two parameters. We shall call this file entry the parameter entry of a file.

Figure 10 is an example of the contents of a record. In this example, 16 words are occupied by files, so that the first record word contains 17. The first file commences in word 2 of the record with its parameter entry; this special entry is illustrated as occupying two words. It indicates that the first file contains two single word entries, whose contents here are 6 and 11. In particular, this first file is a directory and its entries contain the relative addresses of two other files. For instance, in word 11 we find the parameter entry of a file composed of two file entries of two words each.

Quite naturally, the question arises as to how access to a particular file entry may be achieved. Access to a particular file entry entails selecting the appropriate record (i.e., the address of its register) from the catalogue, and then making selections from each directory to reach the desired file. Once having accessed the file, by using the

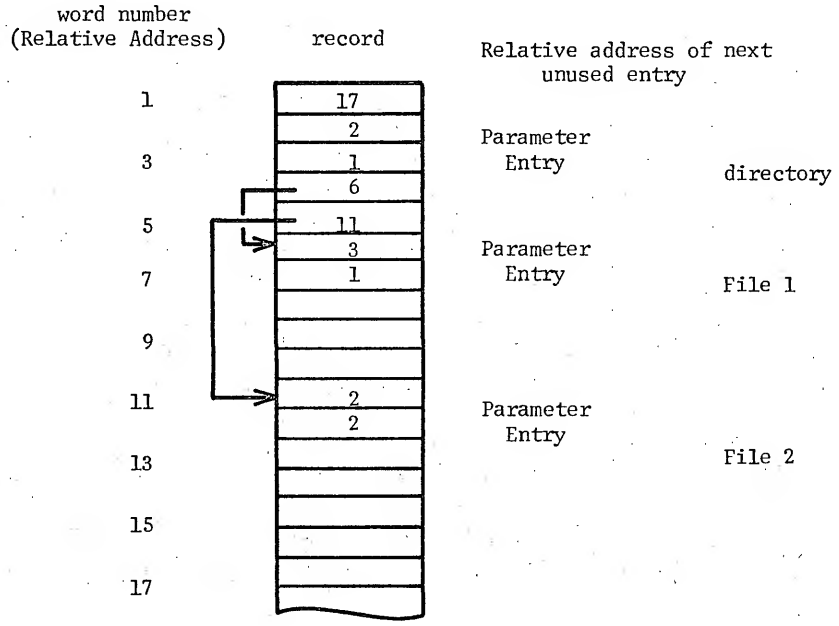

Figure 10. A Record.

number of words per file entry, reaching any particular file entry has been reduced to a problem primarily in counting.

The required selections to be made from the catalogue and directories are specified by a vector, LISTER. The first word of LISTER is its dimension, or in other words one plus the number of choices. The record to be selected from the catalogue is indicated in the second LISTER word. If the dimension of LISTER is N, then the next (N-3) components of LISTER specify selections from the directory hierarchy. (There is no requirement that directories need be employed if a record is to contain only a single file.) Finally, the last LISTER component, the Nth, identifies the particular entry from the file selected. For example, if the record shown in Figure 10 is record number 10, then the LISTER vector (4, 10, 2, 1) will result in the access of the file entry commencing at relative address 13. (Word 1 indicates the length of the LISTER vector which is 4. The 10 says the address of the register for this record is in the tenth entry in the catalogue. The 2 says we are to go to entry 2 of the initial directory which points us to file 2. The 1 indicates we want the first word of the file which is word 13.)

The LISTER vector provides sufficient information for accessing an entry in an existing file, as in the transfer of data from a file entry. When data is to be stored in a file which until this point has not existed, supplemental information is required about the size of any new directories, the size of the new file and the number of words per file entry. This supplemental information is required to insure that sufficient space is reserved (since later entries may be added) for each new directory and file added to a record. This information is provided by a second vector supplied by the user, the length of which

is 2+ the number of directories. If LISTER(1) is N, then the number of components in the auxiliary vector is (N-1). Note that it is necessary only to provide the number of entries in each directory and not also the directory entry size since by convention the directory entry size is permanently fixed at unity. Directory sizes account for the first (N-3) components of the auxiliary vector. The remaining two components are respectively the number of file entries and the file entry size. The supplemental information is of utility only for those directories which have not previously been established. Components corresponding to existing directories are ignored.

Consider a file processing scheme involving the access of many entries on a particular file. The catalogue and directory selections, if repeated for each file entry, would constitute needless repetition since access of the same file would be the result each time the selection sequence is executed. Thus, it is desirable to provide the means of reaching another entry in a file from a file entry that has already been accessed. The move relative to a given file entry to reach another is specified by providing the distance (i.e. number of file entries) of the move and the direction of the move. The LISTER vector is the vector for this information. LISTER(1) is set to 1, indicating the move-relative mode. LISTER(2) contains the displacement as a signed integer, with positive and negative values indicating forward and backward displacements respectively. The LISTER vector (1, 1) would access word 14 of the previous example. Repeating with (1, 1) would then access word 15, and so forth.

If movement relative to a particular file entry is to be accomplished, one must know exactly the location of that file entry. Unfortunately, knowing the location of a file entry involves more than simply knowing

its absolute or relative addresses, though these addresses are certainly essential. It is also necessary to have available the address of the record segment, the sequence number in the record of the record segment, the register segment address and the particular record segment word referencing the record segment. This is by no means a complete list, for many other parameters have been found to be of utility in expressing positions within files or of utility in executing the relative move itself. To provide a storage medium for these parameters, a vector, JCLOAD, has been created. This vector consists of 30 components, each of which is described by the comments to program C4ADRS in Appendix A. For most users it will be sufficient to know that the vector exists and is provided by the user, and that user changes to the vector are prohibited if the relative movement option is to be exercised.

As a result of the sequential appearance of file entries within the files, no verbs for link manipulations are required. In fact, the user is provided with only three verbs for performing manipulations of file storage. These are STORE to store data in a file entry, FETCH to retrieve a copy of data in a file entry, and FIND to locate a file entry containing a particular data value pattern. The specification of the data fields to participate in the data transfer operations is accomplished identically as in the description in the preceding section for COAST. REMOTE does require certain restrictions with respect to data types. Table 2 gives the data types, with their LEND components, which are necessary. Beyond these four data types, the user is free to organize the LEND in any convenient fashion. The V in Table 2 indicates locations where the user may exercise choice.

One eventuality of file storage has until now been neglected. It is possible that a file entry occupying several ALLOC words may not

TABLE 2

LEND Components Required by REMOTE

Data Type	LEND[a]	Use
1	1,0,1,0	Catalogue and register forward link
2	2,0,1,0	Catalogue and register backward link
3	1,V,V,V	First field is number of entries in the file
4	V,V,V,V	Last field is the number of words per file entry

[a] First word of data type, last word for data type - if zero last word is end of list entry, shift, mask.

exactly fit at the end of a record segment. Two policies are possible. One, the file entries are required to be continuous, risking the waste of a few words per record segment. Two, the partitioning of file entries between record segments is to be allowed. If the file entries are not small with respect to record segment size, the latter policy is clearly more desirable with respect to efficient use of memory. Since the sizes of file entries and of record segments are choices permitted to the user, and since the restriction of the user's freedom to organize a file structure was to be minimized, the partitioning of file entries is allowed by REMOTE. As with the JCLOAD vector, the user need not be aware of file entry partitioning to successfully employ REMOTE. The user may prevent partitioning by a judicious choice of the record segment size or of the number of words required by the parameter file entry initiating the file. This latter play is implemented by the word index selection in the LEND component for data type 4. The parameter entry (See Figure 10) is structured with data type 4 concluding the entry. Thus, by adjusting the number of fields subtended by data type 4, it is possible to regulate the size of the parameter entry without otherwise disturbing its contents.

* III.3.c. NETPAC

The basic network structure has been discussed in Section II.2.a. As noted there, certain data fields are essential to the network structure. That is, the links alone are insufficient to adequately define a network structure.

Table 3 is a list of the data fields augmenting the link fields. Of these additional fields, only data type 3 and the first two fields of data type 5 are of an essential nature. In order to differentiate nodes from diverger entries, some unambiguous feature must be provided

TABLE 3

Auxiliary Data Fields Required by NETPAC

Data Type	LEND[a]	Data Field	Use
3	1,V,V,1+	1	Identification flag (Q diverger entry, > 0 node)
4	V,V,V,V	1	Trace key
		2	Sub-nodal network trace key
5	V,V,V,V	1	Number of forward paths leaving node
		2	Number of backward paths leaving node
		3	Counter employed during trace

[a] First word in list entry for data type, last word in list entry for data type - if zero last word is end of list entry, shift, mask.

to each. This feature is a flag, which is zero for a diverger entry. The first field of data type 3 serves as the flag. The + symbol in the LEND for data type 3 indicates that the mask may encompass more than a single bit. The first two fields of data type 5 contain the number of paths leaving a node in each direction. These fields are absent from diverger entries.

The remaining data fields listed in Table 3 are not essential to the network structure, but are required if the network is to be traced using the verb NEXT.

The trace strategy employed is somewhat involved. Each trace is assigned a unique trace key. We shall call this key the master trace key. The purpose of the key is to flag the nodes which have been encountered by the trace so they may be distinquished from those which have not yet been reached. This is necessary since several paths may lead to the same node. Upon the first encounter of a node, which is indicated by its trace key being unequal to the master trace key, the trace key is set equal to the master key and the counter in field 3 of data type 5 is set to unity. Successive encounters with this node will be indicated by the trace key matching the master key. The counter is incremented by one at each encounter of the node. When the counter matches the first field of data type 5 for a backward trace or the second field of data type 5 for a forward trace, a node has truly been "reached." Further, it is only upon meeting this criterion that the links leading from a node in the direction of trace may be examined.

The trace strategy was dictated primarily by the needs of the interpreter in evaluating the components of a solution procedure. No component may be evaluated until all preceding components have been evaluated. That is, no node is considered as reached until all paths

leading into the node have been followed. Figures 11 through 11e illustrate the steps in tracing a simple network. The data fields appear in the nodes shown in the order of their occurrence in Table 3. For simplicity, each is assumed to occupy an entire word. An * appears beside each node as it is reached.

Let us consider Figure 11c. The count does not match the number of backward paths. This causes the trace procedure to backtrack and consider the path parallel to B. For more complex networks, it is necessary to distinquish the parallel paths yet to be considered from those which have already been inspected. This distinction between paths is facilitated by an auxiliary push-down list. Each entry on this list points to a diverger entry. These diverger entries are the first on their respective divergers which have not yet participated in the trace. The top member of this list always points to the last parallel path encountered and the first to trace when the current path terminates.

It may be noted that the sub-nodal network trace key played no part in the trace illustration. This trace key is the master key for networks existing as auxiliaries to network nodes. The import of the network within a network will be pursued in Chapter IV. When the sub-nodal networks are present in a network structure, the trace procedure accounts for their presence by entering each auxiliary network just prior to advancing to the next node on the main list. For example, if node A of the trace example presented in Figures 11 through 11e possesses a sub-nodal network, node B is not considered to directly follow A in the network trace. Rather, the first node of the sub-nodal network follows A in the trace. A unity identification flag identifies nodes possessing sub-nodal networks. All nodes possessing flags greater than unity are not permitted sub-nodal networks.

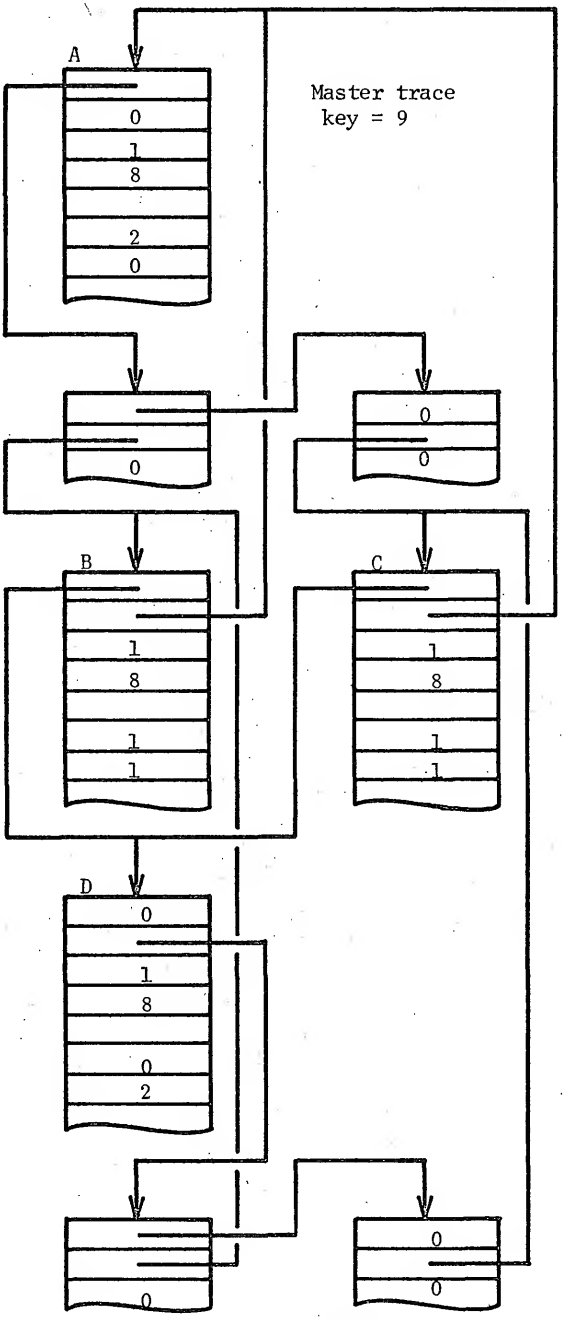

Figure 11. Trace (Start).

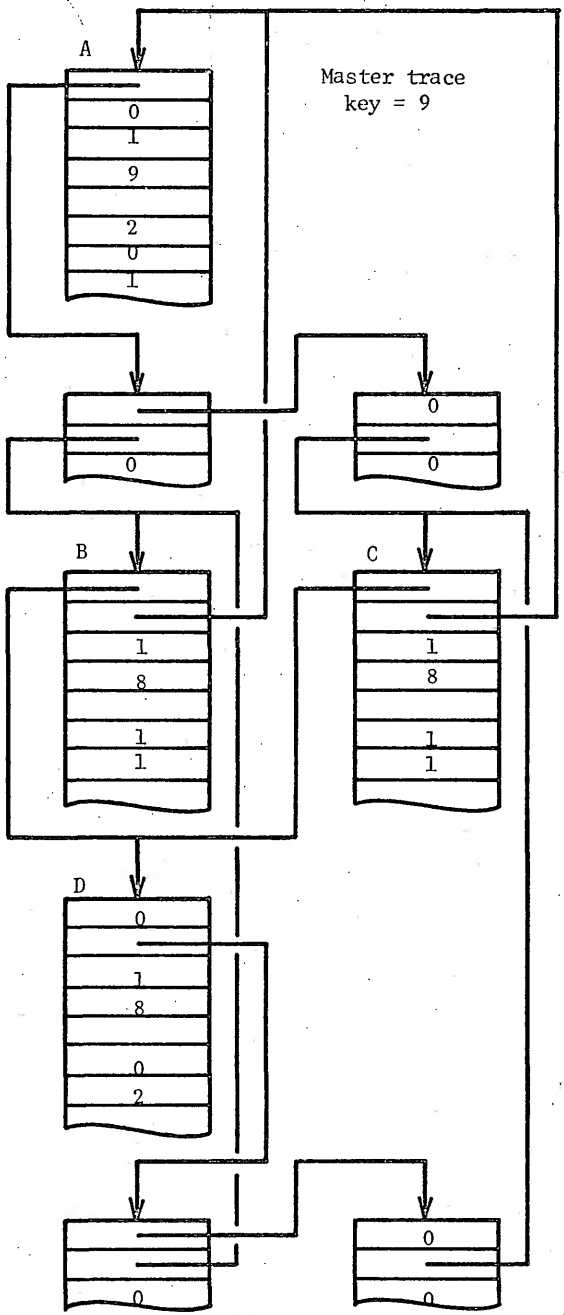

Figure 11a. Trace (Step 1).

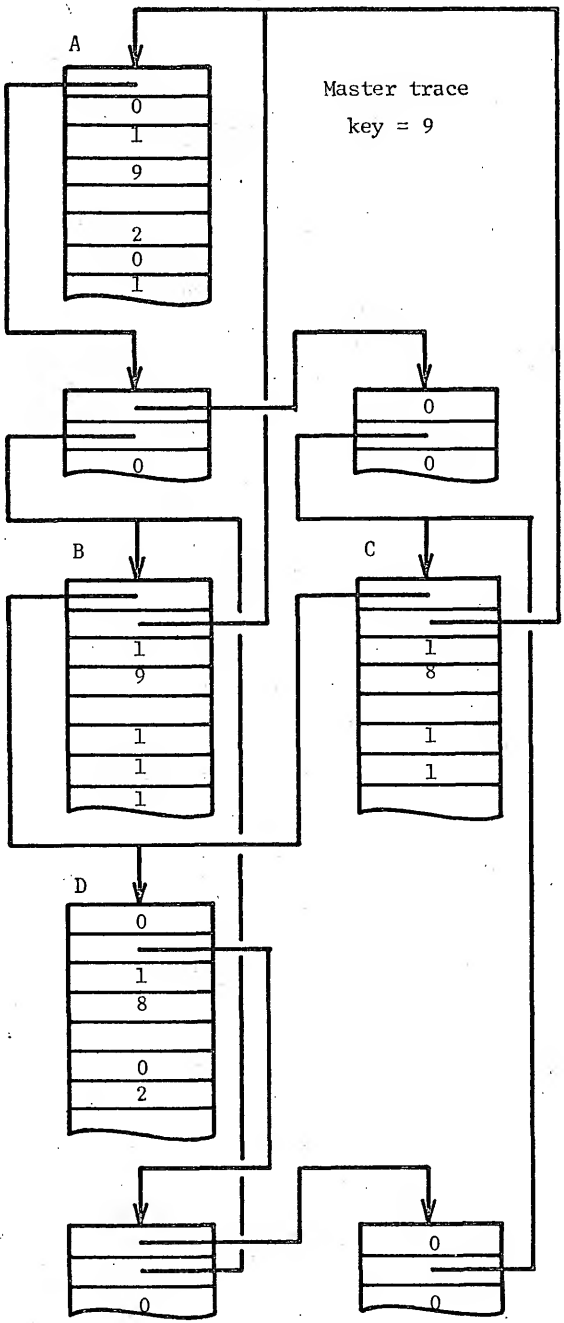

Figure 11b. Trace (Step 2).

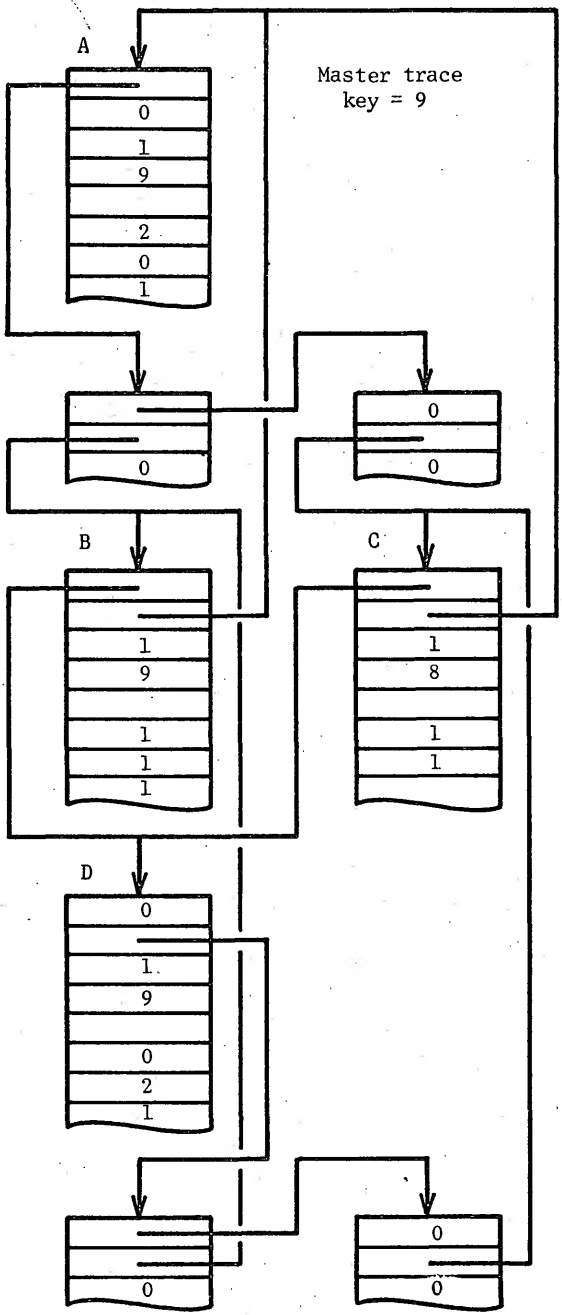

Figure 11c Trace (Step 3 - no node selected).

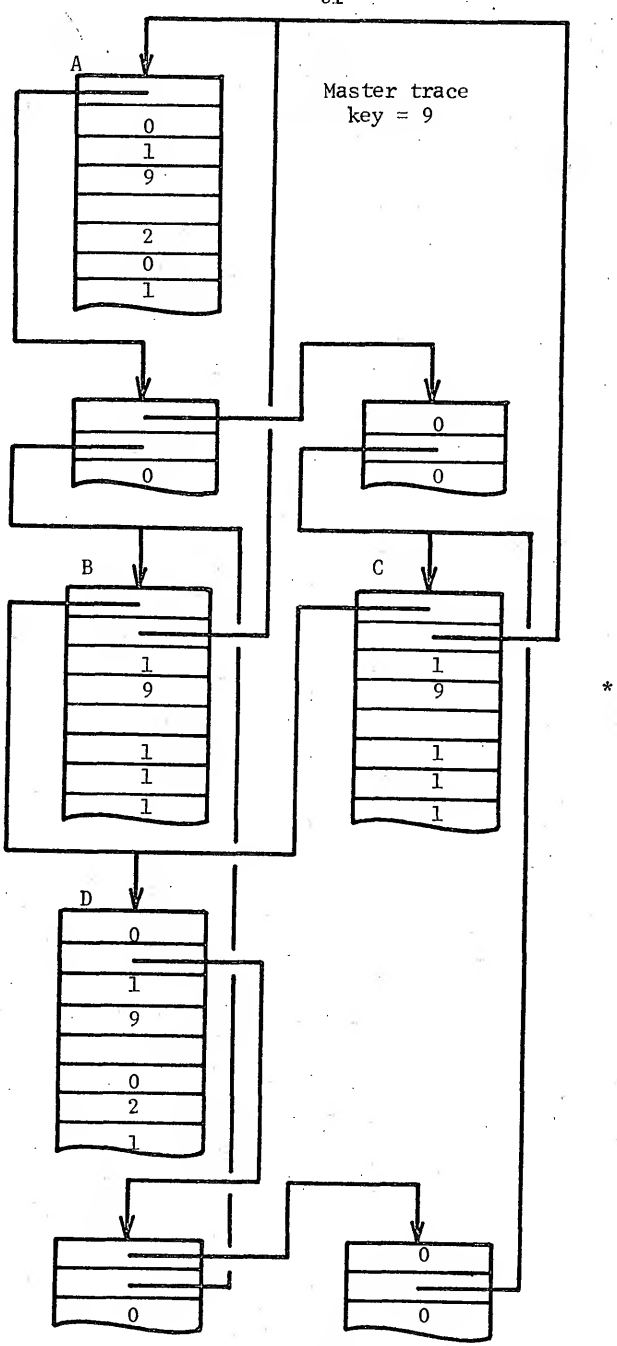

Figure 11d. Trace (Step 4).

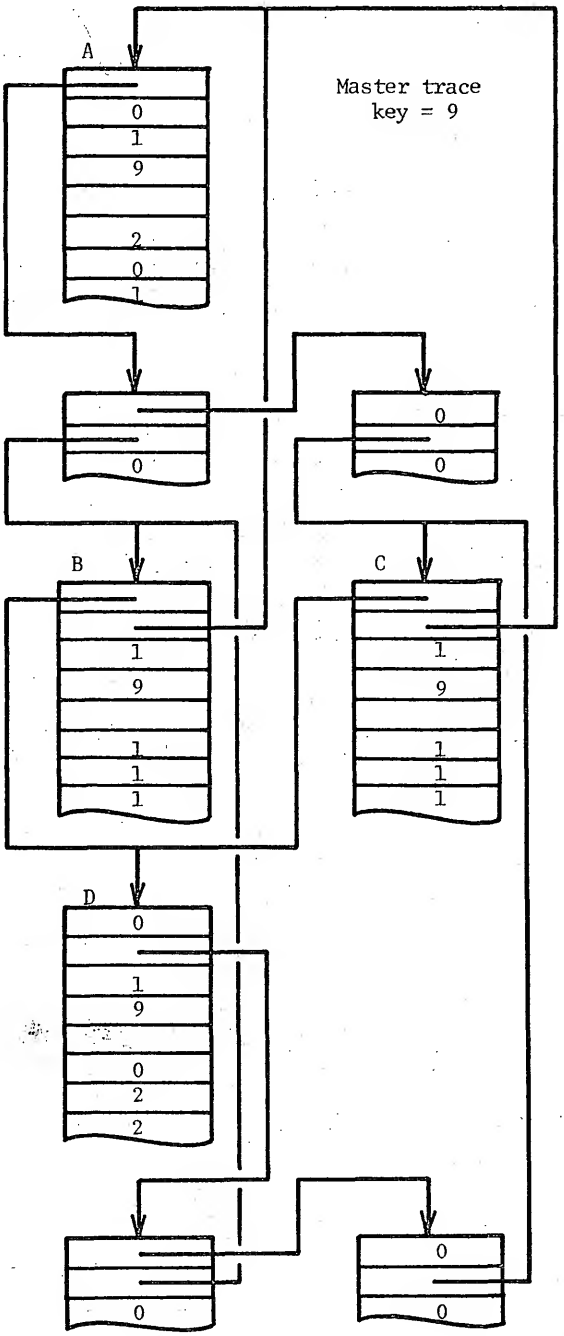

Figure 11e. Trace (Completed).

As a result of networks within networks, the auxiliary list employed by the trace procedure must be complicated somewhat. The paths yet to be inspected at each level in the network must be segregated from those of all other levels. This segregation is accomplished by a list composed of one entry per network level. Each entry points to a list indicating the remaining parallel paths on a particular level. The manipulation of this auxiliary list structure is not required of NETPAC users.

The subroutine NEXT is the NETPAC verb providing the trace capability. NEXT requires only that the user indicate the address of a current node and the value of the master trace key. NEXT performs all of the network and auxiliary list manipulations necessary to provide the user with the address of the next node in the trace sequence.

The COAST verbs require SPUR vectors to indicate the size of list entries and the list type. In order for the NETPAC verbs to employ the COAST verbs, it is necessary to provide a battery of SPUR vectors, since many different sizes of list entries appear in the networks used in GENDER. One SPUR is required for each list entry size. To satisfy this requirement, a sequence of SPUR's graduated in sizes from a single word list entry up to the largest possible list entry size are stored in a continuous ALLOC partition. It is expected that this SPUR block will typically be less than the ALLOC segment size.

Having the SPUR block only solves half the problem. To be able to select the proper SPUR, one must know the sizes of the various list entries constituting the network. A vector, which we shall call the information block, contains this data. The values for each information block component are provided as data by the user. Only three pair of

the 28 information block components are required by NETPAC. These pair are components 8-9, 20-21 and 22-23, and are associated with networks employing list types 2, 6 and 5 respectively. Networks have been restricted to list types 2, 6 and 5 primarily as a programming convenience since the use of NETPAC external to GENDER is doubtful. Information block components 8, 20 and 22 indicate diverger entry sizes, while components 9, 21 and 23 are node sizes. The identification flag distinguishes nodes from diverger entries. Although more than one type and size of node may appear in a network, NETPAC requires access only to data types 1 through 5. Since every node contains these data fields, the SPUR for any node will suffice NETPAC. For the user's convenience, information block components are reserved for the sizes of the other nodes permitted to list types 2 and 5. Discussion of the remaining information block components is deferred to the particular chapters to which they are relevant.

The information block introduced in the preceding paragraph resides in ALLOC. The address of this block is recorded in the seventeenth ALLOC word. Consequently, access to information block data is relatively simple and the data is available to all GENDER subroutines sharing ALLOC. It would seem advisable to make similar provisions for the SPUR block. In fact, a vector, NIMBL, has been invented to contain the addresses of the network and the SPUR block. NIMBL also contains the value of the master trace key. The address of the NIMBL, thus, furnishes sufficient data to permit the access and manipulation of a network.

Table 4 is a list of the NETPAC verbs. BREAK and COUPLE appropriately adjust the path counters, as well as performing the necessary link manipulations. One node to be separated from a second via BREAK

TABLE 4

NETPAC Verbs

Name	Function
BREAK	Breaks the links between two nodes
COUPLE	Connects two nodes
LNKBNT	Gets a copy of the backward link
LNKFNT	Gets a copy of the forward link
NEXT	Performs trace
SEARCH	Employs NEXT to search a network for a specified pattern of data values

must be specified by its absolute address. Although the second node may also be specified by its absolute address, it may be designated by reference to a path leading from the first node. Referring to Figure 11, node A may be separated from node C by providing BREAK with the addresses of both A and C, or with the address of A and the integer 2 indicating the second diverger entry. The path specification mode is available to both forward and backward directions. That is, A may either precede or follow C. BREAK is designed to provide the calling program with the path position if the addresses of both nodes are specified, or with the address of the second node otherwise. This feature has proven to be of use in the algebraic package, GALAP.

COUPLE requires the specification of the addresses of both nodes to be connected and the specification of the path positions. While the order of diverger entries is of little consequence to solution procedure network, the arrangement of parallel paths is of considerable importance in GALAP. Consequently, COUPLE has been designed to permit selective path placement.

The verb SEARCH provides the capability to search a network for a specified pattern of data values. The data values and the corresponding data fields are provided to SEARCH identically as for the COAST verb LOCATE. SEARCH employs NEXT in performing the network trace. Networks possessing a single starting node and a single terminal node may be readily searched in either direction. However, a network having multiple terminal nodes cannot be completely searched in the backward direction. The selection of a terminal node to serve as the initial trace node excludes from the trace, at the very least, the other terminal nodes.

* III.3.d. SIMPAC

Section III.2.b provided a glimpse at the sparse incidence matrix structure. This section will further detail this most important data structure.

The ordinates of an SIM (sparse incidence matrix) are applications of REMOTE. However, this need not have been the case. The ordinates might simply have been continuous partitions of ALLOC. An ordinate of 1,000 entries would require a maximum of approximately 9,000 words. This would constitute a demand for a buddy unlikely to be available, except when specially provided. The implementation of the ordinates as REMOTE records eliminates the requirement for special supervision of the ALLOC allocation mechanism. Further, the use of a record as an ordinate entails no further sophistication of the REMOTE facilities.

Figure 12 shows a sparse incidence matrix with the ordinates detailed as REMOTE records. This matrix is the same as the one in Figure 5, but shown here in more detail. List type 3 has been selected for the ordinates. A number of data fields are required for each ordinate entry. For convenience, these fields are tabulated in Table 5. A few of these fields require further clarification. The status flag is a relatively small field reserved for use by the solution procedure generation algorithms discussed in Chapter V. When equal to one, the dimension flag indicates the substitution of a pointer to an auxiliary data block for the name in data type 9. The auxiliary data block contains the name, dimensionality and index values as whole word entries each. The name is more properly called a code name. The code name uniquely identifies the occurrence of a function, ER, constraint or variable in the data base SECEDE. SECEDE and the rationale of code names is discussed in Chapter IV. Data type 8 has no significance for

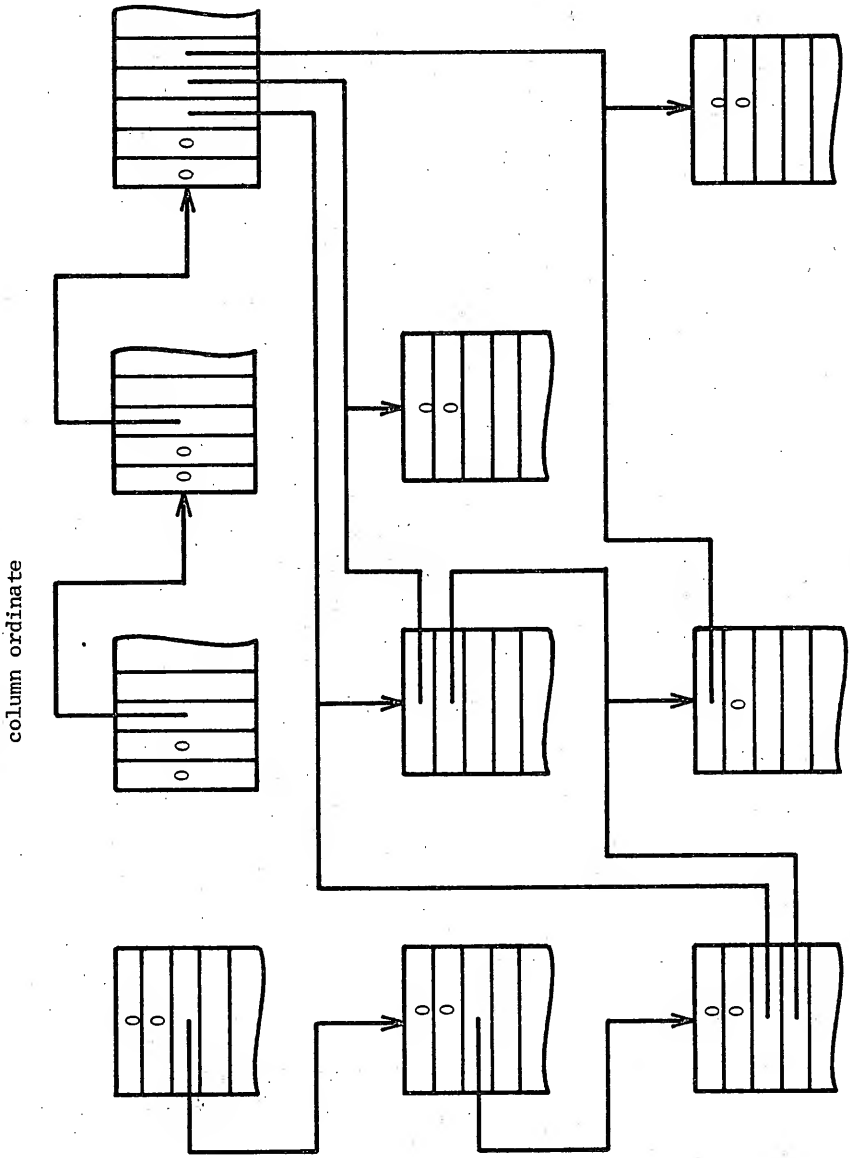

Figure 12. Sparse Matrix.

TABLE 5

Data Fields Required for Ordinate Entries

Data Type	LEND[a]	Use
5	V,V,V,3+	Row/column status flag
6	V,V,V,V	Row/column pointer
7	V,V,V,1+	Dimension flag
8	V,V,V,3+	Identification flag (OER, 1 function, 2 constraint, 3 group)
9	V,V,V,V	Function name
10	V,V,V,V	Number of elements per row/column
11	V,V,V,V	Number of unassigned output variables
12	V,V,V,1+	Multiple output flag
13	V,V,V,V	Output assignment

[a] First word in list entry for data type, last word in list entry for data type - if zero last word is end of list entry, shift, mask.

the column ordinate entries, since all columns represent only variables. The group mentioned in Table 5 for data type 8 will be pursued subsequently in Chapter IV and is more properly called a protected group. For our purposes in this section, it is sufficient to regard a protected group and the ER (for external routine) simply as functions. That is, they are functional relationships involving two or more variables. If the multiple output flag is set to one, the output assignment in data type 13 is replaced by a pointer to a list of output assignments. Two words are required for each list entry. The first contains the link and the second contains the output assignment. An output assignment is simply a row or column number depending on whether the ordinate pertains to columns or to rows respectively.

Each element of a sparse incidence matrix must also carry some information in addition to the links. In particular, it is necessary to know to which column and row an element belongs. This information is provided by fields reserved for the row and the column indices. Other fields are required, but are of a more specialized nature. Table 6 summarizes the data fields appearing in each element. The field for the sensitivity may be omitted at the user's option. The status flag and output selection cost are required for the output assignment and other algorithms. List type 4 is reserved for the SIM elements.

The 28 component information block introduced in the preceding section contains components pertinent to the SIM. Table 7 indicates the information block partition dealing with the SIM.

As in the case of networks, a SPUR block is essential in constructing and performing manipulations on an SIM. The SPUR's required correspond to LOAD vector size (30 words), the element size, ordinate

TABLE 6

Data Fields Required for SIM Elements

Data Type	LEND[a]	Use
1	V,V,V,V	Horizontal link
2	V,V,V,V	Vertical link
3	V,V,V,V	Row index
4	V,V,V,V	Column index
5	V,V,V,3+	Element status flag
6	V,V,V,15+	Output selection cost
7	V,V,1,0	Value of sensitivity

[a] First word in list entry for data type, last word in list entry for data type, shift, mask - If zero entire word is used.

TABLE 7

Information Block Components Pertinent to the SIM

Component	Use
16	Ordinate segment size
17	Number of works per horizontal and vertical link pair
18	Length of an element list entry
19	Length of an ordinate file entry

segment size and list entry sizes from a single word up to the largest required for an auxiliary data block. This largest list entry size is determined as (2 + maximum dimensionality). The maximum dimensionality is contained in the fifteenth information block component. The individual SPUR's appear in the SPUR block in the order of their enumeration above. The point of reference in the SPUR block was selected as the sixteenth word of the block. That is, the address used to access the SPUR block is the first word of the SPUR for a single word list entry. Decrementing this address by five accesses the SPUR for an ordinate segment.

Not only has the SPUR block been adapted from NETPAC, the SIMBL is not unlike the NIMBL. The first two words point respectively to the column catalogue and the row catalogue. The third SIMBL word points to the SPUR block. The description of the SIM structure in detail is completed by stating that the address of the LOAD vectors are contained in the catalogues. That is, the address of the LOAD vector for the row ordinate appears in the second catalogue word.

It is permissible for an SIM to be equipped with more than a single row and a single column ordinate. Working or temporary ordinates are frequently utilized by the solution procedure generation algorithms. Because of the inclusion of the LOAD vector addresses in the catalogues, all ordinates are odd numbered REMOTE records.

The majority of the SIM verbs are specialized in nature, dealing with a single, generally repetitive SIM operation. The SIM verbs are listed in Table 8. The SIM generator, SIMGEN, performs a great deal more than a simple SIM manipulation. SIMGEN uses the list of functions, ER's, etc. belonging to a partition of the solution procedure (called

TABLE 8

SIMPAC Verbs

Name	Function
SIMCIN	Adjust the row and column incidence counts to reflect the removal or reinstatement of a row or column
SIMCPY	Transfer selected data fields from each entry of one ordinate to other selected fields of a second parallel ordinate
SIMDUP	Duplicate the contents of each entry of one ordinate in a second parallel ordinate
SIMEIN	Set all row, column and element status flags to zero
SIMFLG	Set the rodinate and the element status flags of a specified row or column to a selected value
SIMGEN	Generate an SIM
SIMINT	Interchange two parallel ordinates
SIMOPT	Record or erase a row-column output assignment
SIMRTV	Set the status flags of all elements of tear variables to 2 except where they are the output of a row

a group) for which further analysis is required as the basis for SIM generation. Each functional relationship is assigned a row in the order of occurrence in the group. SECEDE furnishes SIMGEN with the incidence and output assignment cost data. SECEDE is described in Chapter IV. In addition to structuring the SIM, SIMGEN also initializes the row, column and element status flags at zero. The utility of the SIMPAC verbs will become more obvious in Chapter IV.

CHAPTER IV

DATA BASE

The information constituting a system of equations and the associated solution procedure must be readily available. One approach to the data base would have been the inclusion of all information relative to an equation set within the solution procedure. As noted in the preceeding chapter, the network structure was adopted for the solution procedure for reasons of flexibility and ease of manipulation. The concept of the unified data base would, during certain operations, encumber the solution procedure with much more data than required. An alternative approach involves providing the general information apart from the specific information pertinent to the solution procedure.

IV.1. Service Module, SECEDE

The general information phase of the data base must at times augment the information within the solution procedure. For instance, during generation of a sparse incidence matrix the variables appearing in an equation must be known. Since this information is not contained within the solution procedure (as SIM generation is one of the few instances when it is required), it must be extracted from the general information. Further, since the equations on the solution procedure are subject to re-ordering, it seems appropriate to require rapid random access to the general information.

The file system, REMOTE, described in Chapter III not only fulfills the requirement for rapid random access, but also permits the release

of ALLOC space by the transfer of data not currently required to mass memory. The application of REMOTE to the storage of information relative to an equation set is termed the service module (SECEDE).

The organization of data within SECEDE required careful consideration. First, the construction of a library of data relative to various processing units is to be permitted. Second, the organization must permit the deletion or inclusion of units from SECEDE. Finally, SECEDE should permit the reorganization of the flowsheet (i.e., connections between units). All of these considerations are essential if the employment of GENDER during the synthesis phase of design is to be feasible. The first two requirements are satisfied by assigning each unit to a separate record. The third requirement is satisfied by restricting all of the information on stream connections to a single record called the zeroth unit. Thus, reorganization of a flowsheet would involve changes only to the zeroth unit unless additional units or unit substitutions are involved as well.

It is, of course, not known a priori what position a unit, which may be from a library, might occupy in the service module. This necessitates a code name assignment scheme for the variables and equations which will produce unique codes. The variables and equations within each unit are sequentially assigned code numbers commencing with unity. The unique code is developed by adding to the code number, as assigned within the unit, the unit number multiplied by an arbitrarily selected scale factor. For instance, variable 5 of unit 9 would be known by the code 905 if the scale happens to be 100. The code 905 differentiates this particular variable from the fifth variable of all other units.

IV.2. Solution Procedure, GENDER List

For the reasons noted in Chapter III, the solution procedure is a network application. It is expected that many solution procedures will involve cyclic calculations. The GENDER list must reflect the existence of such cycles. Special nodes are provided, called groups, which represent the occurrence of a special set of functional relationships. These may be cyclic, or may be grouped because of other common characteristics.

The group node appears in the network as a representation of the group members. Membership within a group is indicated by the nodes of a network called the group body. Each group contains the address of its group body. Groups as well as equations, ER's and constraints may belong to a group body. The group bodies give the GENDER list a dimension of depth - i.e., networks within networks.

The GENDER list must be a complete specification of the solution procedure it represents. That is, the GENDER list must reflect decision variable selection, output set assignment, precedence ordering, tear variable selection, and selection of the method for resolving cyclic calculations. Data fields and/or auxiliary lists are provided to store all of the foregoing information with the exception of the precedence order. The precedence order is reflected by the arrangement of the nodes on the GENDER list.

IV.3. Input/Output Facilities

The initial point for a GENDER list is generally expected to be the crude GENDER list generated by a program called CUDGEL. Each equation, ER and constraint is represented by an entry on the crude GENDER list, but missing are the details and auxiliary lists necessary for a complete solution procedure specification. Though this may be

the usual starting point, it will not always be most convenient. For instance, a solution procedure might be completely developed, but interpretation prohibited by the lack of a value for an algorithm selected decision variable. For operation in a batch machine environment, this eventuality would cause the effort of analysis to be wasted unless recovery facilities are provided. While one obvious solution is to require estimates for all variables prior to initiating analysis to prevent the development of this particular situation, an inordinate amount of effort would be required from the user. This is but one instance of when an analysis might be wasted. Others exist, and enumerating precautions against all is unlikely. The recovery mechanism has been incorporated into the input/output facilities.

While the recovery provisions are not automatic, they do posses the virtue of simplicity. When the development or interpretation of a solution procedure must be abandoned, the service module and the solution procedure may be saved for use at a later time in one of two ways. Both SECEDE and the GENDER list reside in the ALLOC vector. Hence, a copy of the contents of ALLOC will save SECEDE and the GENDER list. The second approach involves the output of only SECEDE and the GENDER list. This latter strategy will greatly reduce the output volume, but this is not the primary advantage. The format of output may be adjusted to produce a much more manageable medium. Particular significance will be attached to each output record and the output records formatted according to content.

The medium selected for storage of service modules and solution procedures for later use is punched cards. Thus, when the solution of a problem must be aborted, the programs SECIAO and GENIAO may be directed to produce respectively the contents of SECEDE and of the GENDER list

in card form. These cards may later be read by SECIAO and GENIAO to resume solving the problem. Observe that a solution procedure, complete in every detail, may be stored in card form as readily as a partially complete solution procedure. In fact, a library of solution procedures may be amassed to eliminate repetitive analysis of problems which are frequently solved.

The format of each card generated by SECIAO and by GENIAO is presented in Appendix A in terms of data formats. This is permissible since the input and output formats are identical. For the convenience of the user, a printed output will always be provided with card output. In fact, a printed only output mode may be selected for both SECIAO and GENIAO should the punched card output not be desired.

IV.4. Implementation Details

The remainder of this chapter delves into the implementation details for SECIAO and for GENIAO. These details will be of utility only to those users wishing to prepare programs which directly access either SECEDE or a GENDER list. Most users should find the program comments for SECIAO adequate to encode properly the statement of the problem as SECIAO data. The printed output of both SECIAO and GENIAO is preceded by a table indicating the composition of each type of output line. A third subprogram, VARIAO, completes the input/output facility package. VARIAO supplies a user with a list of variables for which values are required. VARIAO is provided primarily for use by the interpreter, GLINT, to indicate variables encountered for which values have not been provided.

* IV.4.a SECEDE

Basically, the service module, SECEDE, is an application of REMOTE.

The REMOTE system is founded on the premise that all entries of a file are of the same size. Unfortunately, exceptions to this fundamental premise may arise. For example, SECEDE is required to store functions in terms of the variables, operators and constants of which they are composed. All three entry types require data fields for an identification flag and a code name. However, the variable also requires fields for the dimensionality and, if applicable, the indices. While it would certainly be possible to insist that all file entries representing a function be equal in size, the opportunity for wasting considerable ALLOC space would just as certainly be present. This eventuality would be realized for all functions containing only a few dimensioned variables with respect to the total number of entries.

The apparent inconsistency between storing functions as REMOTE files and efficient memory utilization can be reconciled, albeit artificially. To each file entry add another data field containing the length of the entry. Moving from one file entry to the next would involve adding the file entry length to the current position in the file. Except for the variations in file entry length, this procedure is decidedly reminiscent of the relative move capability already present in REMOTE. In fact, if REMOTE were led to believe that the file entry length is unity, and if the actual entry length is used as the number of file entries to advance, then movement can be accomplished via the REMOTE relative move mechanism.

Before proceeding, we should clearly differentiate the two types of entries discussed in the preceding paragraph. When establishing a file, the JCFINE vector specifies the file entry length. This is a fixed number and is the length employed in specifying the length of a file. The entry of variable size is not a true file entry. It is rather a sequence of one or more words of a file which we choose to

treat as a single entity and to which we attach special significance. Let us assign the acronym ASE to the adjustable size entries, while reserving the term file entry to mean true file entry in the REMOTE sense.

A file composed of ASE's strongly resembles a forward-only list. That is, the length stored in each ASE serves as the link to the next ASE. Consequently, we shall refer to this scheme as relative linking, and to the stored length as the relative link. The last ASE must contain zero for the relative link just as a terminal list entry must contain zero for the forward link. Since the identification flag stipulates the fields within the last ASE, and since the LEND stipulates field placement within the ASE, the zero length specification presents no hindrance to data transfer.

A hindrance to data transfer does, however, exist. The file entry length must be specified as unity to permit relative linking. Normally, REMOTE will not permit data transfer operations to exceed the bounds of a file entry. The ASE's are expected to be multi-word entries. To circumvent this problem, REMOTE was adjusted to permit the violation of file entry bounds if LOAD(29) is set equal to -1. The user must ensure that LOAD(29) is properly set before attempting access to any file. LOAD(29) should be 0 for all files not employing relative linking.

As we noted earlier, an ASE file resembles a forward-only list. Consequently, it is not possible to randomly access the ASE's. This need not be the case. Suppose the relative links are removed from the ASE's and placed at the beginning of the file. The value of the relative links would, of course, be different since the relative link is the number of words to advance from the current position to the ASE.

What we have developed is the notion of a directory, employing relative links instead of relative addresses, which is internal to a file. The term internal directory shall be employed to describe this placement of the relative links.

Files containing ASE's in the list format will be called sequential access files, SAF's. Files containing unlinked ASE's and an internal directory will be called random access files, RAF's. The RAF does not provide a storage capability which can not be duplicated by an ordinary REMOTE file structure without recourse to ASE's. This could be accomplished by establishing each ASE as a separate file and providing a directory permitting random access to the separate files. However, this structure demands that the relative access be accomplished at the expense of repeating all catalogue and directory hierarchy selections for each access. The RAF structure permits the access computations to commence with the internal directory, since this directory and the ASE's are actually all members of a single file making the REMOTE relative address capability applicable. That is to say, the RAF access time would be generally shorter.

SECEDE consists of at least five records, each record containing from one to five files. These files include all three types; ordinary REMOTE files of equal sized entries, SAF's and RAF's. Each record will be given individual attention. In the discussion to follow, the notation (t i f j) will be used. The letters i and j represent integers indicating data type and data field respectively. The letters t and f should be translated as type (i.e., data type) and field. If we were to speak of a data field (t5f9), we will be considering the ninth field of data type 5. On occasion it may be convenient to expand our field designation shorthand to include a range of fields for a single data

type. For example, (t5f7-9) is translated as fields 7 through 9 of data type 5.

Armed with the above bit of cryptography we are prepared to inspect the purpose and contents of record one. Tables 9 through 11 may be of assistance in this discussion. The first record consists of a directory and two files. The files contain respectively decision and tear variables and are of the SAF type. Each of the ASE's contain the data fields (t1f1-3), plus an additional two words for each degree of dimensionality. The two word allocation for each index is required to permit the specification of minimum and maximum of an index range. A single ASE may represent, for a dimensioned variable, a single component or many components. Each word reserved for an index contains the fields (t9f1, t10f1, t11f1, t12f1, t13f1, t14f1, t15f1), which correspond to the seven constituents permitted in an index calculation as discussed in Appendix B. These constituents, in the order of the fields, are mapping flag, mapping index, operator flag (0 for multiplication by scale and 1 for division by scale), sign flag for scale (0 for positive and 1 for negative), scale, sign flag for offset (0 for positive and 1 for negative) and the offset. The mapping flag may be either 0 for no map, or may be 3 indicating mapping to another index of the same variable. If the mapping flag is 0, data types 10-14 are ignored and the offset is taken to be the index value. As a matter of convention, all data structures requiring the seven part indices will employ data types 9-15 exactly as described here.

The second and third records in SECEDE each contain only a single file. These files are ordinary REMOTE files composed of file entries all equal in size. Each file entry contains alphameric characters forming the name of an operator in the case of record two or the name

TABLE 9

Data Fields for SECEDE

of a method in the case of record three. A method is a user prepared subroutine for supervising the convergence of a cyclic calculation during interpretation. The notion of a method is further pursued in Chapter VII. The entries of records two and three may be described as (tlfn), where n is the number of words per name.

The processing units are regarded in GENDER to be completely separate entities. To form a processing plant, the units must somehow be connected together to permit the transfer of material between the units. This physical connection of units is represented algebraically by a connection equation. For example, VCN201 = VCN422 is a connection equation relating variable code name (VCN) 201 to variable code name 422. If the scale factor for unit numbers employed in developing the unique code names is 100, then this example indicates the equality of variable 1 of unit 2 with variable 22 of unit 4. It is entirely possible that a single variable may appear in several connection equations. That is, many variables may share a common value. This leads to the notion of a common storage location for the value of all variables sharing a common value as stipulated by connection equations. Further, if the unit variables are connected by the sharing of value storage locations, the need for explicitly stating the connection equations in either SECEDE or the GENDER list is eliminated.

Unit 0 is contained within record four of SECEDE and is reserved for common variables. This record contains three files. The first file is an RAF and contains data relative to the dimensionality of the common variables. The similarity of function between this file and the DIMENSION statement in FORTRAN suggested the name declaration file. Apart from those containing relative pointers, each declaration file ASE will contain the fields (tlf(2+d)), where d is the dimensionality.

Field (tlf2) contains the dimensionality. The d fields reserved for the indices indicate the maximums of each index. The field (tlfl) is the pointer to the value storage location. The field is an absolute pointer which is computed by the program SECIAO during the establishment of SECEDE. In particular, the absolute address corresponds to an entry of the common variable value file. Although this file is only the second on the record, a LISTER of (4, 4, 3, 1) must be employed to permit access. The second directory entry is reserved for the number of common variables. The variable value file consists principally of entries of the form (tlfn), where n is the number of words per floating point value. All values are in floating point format. While a single entry containing (tlfn) is satisfactory for scalar variables, many such entries are required for dimensioned variables. If a dimensioned variable appeared on the file expanded into its components, the access of any variable, appearing later in the file than the dimensioned variable, would require knowledge of the number of dimensioned variable components. That is to say, the random access feature of the file is greatly compromised. As an alternative, let us consider partitioning the variable value file into two divisions. The primary division appears first in the file and contains one entry per variable. For scalar variables, the primary entry is simply the value. For dimensioned variables, the primary entry is of the form (tl7fl, tl8fl), with the fields containing respectively the integer 21 and a relative link to the first of a sequence of entries in the secondary partition. This sequence of entries encompasses the values of every component of the dimensioned variable. The integer 21 is provided as a safety measure but has proven to be of only occasional utility.

The third file of unit 0 is the common variable name file and is referenced by the fourth directory entry. The entries of the variable name file are identical to those of the operator name and method name files of records two and three.

Each record following record four is designated as a unit. The unit records are considerably more complex than any record we have previously considered.

A unit record comprises eight major file divisions, four of which are further subdivided by second level directories. The individual files are all of types we have already considered in the first four records. The first entry of the first level directory references an eight entry second level directory. Entries 1, 3, 5 and 7 of the second level directory reference declaration files for variables, ER's, equations and constraints. Directory entries 2, 4, 6 and 8 are respectively reserved for the numbers of variables, ER's, functions and constraints. The four declaration files are essentially the same as the common variable declaration file of record four.

The variable declaration file requires the addition of a data type 1 field between the value address and the dimensionality, making each entry of the form (tlf3+d). This additional field is reserved for the code name of a common variable. When a unit variable is declared common by a non-zero (tlf2) field, the common variable code name and value supercede those of the unit variable during preparation and interpretation of the GENDER list. That is, the common declaration substitutes for the connection equation. The remaining three declaration files require only the fields (tlf1+d), where the field (tlf1) is the dimensionality.

The second and third first level directory entries refer to the variable and constant value files. The variable value file is identical to the common variable file of record four. The constant value file is quite similar to the variable value file, except that all constants are single entities making the provisions for dimensioned variable components unnecessary for the constant variable file.

The ER and the variable name files correspond to the first level directory entries four and five. The name files are structured identical to the files of the second and third records.

The first level directory entries remaining correspond to the ER, equation and constraint files. Let us consider the equations. Each equation is recorded on a separate SAF. The equation SAF's are recorded on the equation directory, which is in turn recorded on the first level directory. For example, the LISTER vector (5, 5, 7, 1, 1) would be appropriate to accessing the first equation of unit 1. The equation SAF is not unlike the decision and tear variable SAF's. The first ASE pertains to the equation and is of the form (t1f3, 2xd). The field (t1f1) will always be the relative link in an SAF. The fields (t1f2) and (t1f3) are respectively the number of outputs and the dimensionality. The indices are recorded exactly as they were for the decision and tear variables. Each ASE after the first ASE represents a variable, operator or a constant. A field, (t5f1), is employed as an identification flag . Flag values range from 0 to 2 and correspond in order to an operator, a variable or a constant. The operator and constant entries are identical and consist of the fields (t1f1, t5f1, t16f1), with (t16f1) containing the operator or constant code name.

The variable ASE contains the fields (t1f1, t5f1, t7f1, t8f1, t19f1, 1xd). In order of appearance commencing with (t7f1) these fields are

an output selection cost flag, variable code name, dimensionality and the indices. The algorithm employed for output set assignment permits the use of weights to influence the output set selection process. The weights represent a cost of assignment and are scaled from 0 to 10. One word is reserved for each index which are in the seven part format described for the decision and tear variable files. The ER and constraint files are identical to the equation files except that operators and constants do not appear in the ER files.

* IV.4.b. SECIAO

In the previous chapter, it was noted that certain support structures to the sparse incidence matrix were of utility. Much the same situation exists here for SECEDE. The file entries are of varying compositions and sizes, suggesting the use of an information block to serve as a reference table.

The twenty-five word information block, mentioned in Chapter III with respect to networks and SIM's, is again pressed into service. Information block components 1 through 7 are reserved for data pertinent to SECEDE. Table 12 list these components. It should be noted that component 2, the length of a floating point value, is uniform throughout SECEDE. All variables will either all be single precision or all be double precision.

Apparently all of the ALLOC space required for SECEDE is in the form of record segments, making the use of a SPUR block a somewhat dubious feature. This is, however, not necessarily the case. In the previous section, the description of the variable declaration ASE's included a field reserved for the address of a storage location. While this is perfectly satisfactory for scalar variables, a single address may not be sufficient for a dimensioned variable. In particular, if

TABLE 12

Information Block Components Pertinent to SECEDE

Component	Use
1	Length of a record segment
2	Length of a floating point value
3	Length of a subprogram (ER or method) or variable name
4	Length of a variable ASE excluding indices
5	Length of a constant ASE
6	Number of record segments requested by each call to NEWCEL
7	Scale factor applied to unit numbers to develop unique code names for variables, constants, ER's functions and constraints

the value locations reserved for a dimensioned variable extend over several record segments, the single address will be inadequate. This situation is remedied by establishing for each dimensioned variable a dimensioned variable address resolution block, DIVARB. It is the address of the DIVARB which appears in the declaration file for a dimensioned variable. The DIVARB encompasses (2+d+r) words, where d is the dimensionality and r is the number of record segments containing values of the components to a dimensioned variable. The first word of the DIVARB contains the dimensionality d. The next d words contain the ranges of the indices. The (d+2)nd DIVARB word is called the offset. The offset is the integer which when added to the address of the record segment containing the first variable component will give the address of that first variable component. For example, suppose that the values of a dimensioned variable commence with the 2902 nd word of ALLOC. Further, suppose the record segment address is 2861. The offset to be recorded in the DIVARB would be 41. The remaining or DIVARB words are reserved for record segment addresses. The DIVARB permits rapid address resolution for a dimensioned variable component. The variable value file is a linear storage medium necessitating the conversion of multi-index sets into a single index. That is, the set of indices for an array component must be converted into the single equivalent index for the storage of the array as a vector. Except for the length of a record segment and the number of words per value, all of the data necessary for both the index conversion and the address resolution is contained within the DIVARB.

The need for a SPUR block is now some what obvious. The size of the SPUR block (i.e. the number of SPUR's required), however, is not clearly defined. The DIVARB size depends not only on the dimensionality,

but also on the number of components of a dimensioned variable. The dimensionality and number of components will remain unknown to SECIAO until input of the variable declarations commences. Although it would be possible to complete variable declaration input before preparing the SPUR block and establishing the DIVARB's, it is unnecessary to do so and may even result in the wastage of ALLOC space. A SPUR stipulating a list entry size larger than one half the ALLOC segment size will waste a portion of each segment allocated. This cannot be avoided. However, the SPUR itself can be eliminated. We shall reserve a single SPUR for all large DIVARB's, employing it by altering the list entry size contained in the fourth SPUR word. The SPUR block adopted for SECEDE consists of (2+(ALLOC segment size)/2) five word SPUR's. The first SPUR is provided for the requisition of DIVARB's larger than one half of ALLOC segment size. The second SPUR is appropriate to record segment acquisition. The remaining SPUR's are graduated in list entry size from 1 to one half of ALLOC segment size. It is the address of the SPUR for the record segment which is considered to be the address of the SPUR block.

The use of REMOTE requires a LOAD vector. In particular, two LOAD vectors are required by SECIAO for manipulating SECEDE. The LOAD vectors are furnished as a single vector 60 words in length which is called the LOAD block.

The entire service module is bound together by a service module block, SECBL. The first word of SECBL contains the address of the SECEDE catalogue. The remaining SECBL words are pointers to the SPUR block, the LOAD block and to an allocation of space reserved for index calculations.

* IV.4.c. GENDER List

We have already established that a GENDER list is actually a network. However, the GENDER list is far from being a simple network. This complexity includes, but certainly extends beyond, the concept of depth discussed briefly in Section IV.2. To assist in describing the details of the GENDER structure, Tables 13 and 14 summarize the data types and list entries embodying a GENDER list.

The fundamental GENDER list building blocks are nodes representing equations, ER's or constraints. Nodes in this category contain the fields (t1f1, t2f1, t3f1-2, t4f1-3, t5f1-3, t16f1, t17f1, t18f1, t19f1, t20f1, 2xd). The fields (t3f2, t4f3, t16f1, t17f1, t18f1, t19f1,t20f1, 2xd) are additional to fields required of all NETPAC applications. The value of the flag (t3f1) is 2 for these basic nodes. The identification flag (t3f2) indicates the exact character of the node. Its values may range from 0 to 7 and correspond in ascending order to an ER, an evaluated ER, an equation, solved equation, an evaluated equation, a constraint, a solved constraint and an evaluated constraint. A solved equation relates an output variable to a set of one or more input variables. The solved equation is simply an algebraic rearrangement of an equation. The solved constraint has been algebraically solved for a particular variable, making it analogous to an equation. An evaluated equation is best explained by example. Suppose we have an equation of the form

$$F(x,y,z) = 0$$

If we evaluate the equation for a given set of x, y and z values we obtain

$$F(x,y,z) = f$$

where f represents the value of the equation at x, y and z. If we were

If we were to include a "variable" representing f in the original equation F, and if we were to perform whatever algebraic rearrangement might be required to solve for the "variable" f, the result would be an evaluated equation. The evaluated ER and evaluated constraint are analagous to the evaluated equation. Evaluated equations, ER's and constraints appear only in cyclic calculations where they are employed for adjusting the values of tear variables.

In order to consider the algebraic rearrangement of, for instance, a function, it is necessary to have a list of the components to the equation. This list is called the link editor list, the pointer to which is field (t16f1). Further discussion of the link editor list is momentarily deferred until the discussion of the nodes currently under consideration has been completed. The fields (t17f1), (t19f1) and (t20f1) are respectively the code name (for the equation, etc.), the dimensionality and the number of outputs. Two words are served for each index, to record an index range in the seven part format. The pointer to the output variable list is field (t18f1). The output variable list consists of forward-only linked list entries containing the fields (t1f1, t2f1, t3f1, t21f1, d). Field (t21f1) is the output variable code name . The flag (t3f1) will normally be 0, except when an output variable is also a tear variable and the function, ER or constraint is to be evaluated rather than solved for its output. In this case, the flag will be 2. The dimensionality is recorded in field (t2f1). One word only is reserved for each of the seven part indices.

The link editor list of an equation must contain distinct entries for variables, operators and constants. A flag, data field (t3f1), is employed to identify the type of equation component represented by a list entry. The flag values 0, 1 and 2 correspond to operator, variable and

constant list entries.

The operator and constant list entries are identically structured as (t1f1, t2f1, t3f1, t21f1). Data type 1 is the forward link, and data type 3 has already been discussed. The field (t21f1) contains the code name of the operator or constant. For the constant, field (t2f1) is an absolute pointer to the constant value. For an operator, this field specifies the order of the operator.

A variable entry on a link editor list contains the fields indicated for a constant plus the field (t22f1) and one word per degree of dimensionality. The field (t22f1) is the dimensionality. The pointer to the variable value is (t2f1), and the variable code name appears in (t21f1).

So far, we have considered variables, constants and operators with respect to the link editor list. One might be tempted to conclude that these three entries are sufficient for all functions, ER's and constraints. However, this is not the case. Recall the notion of an evaluated equation. For an evaluated equation, a link editor list entry must be provided to represent the equation value. This entry is identical in structure to the variable list entry. In fact, the data fields serve the equation precisely as they do a variable.

A further entry type may be seen by considering the result of an algebraic rearrangement of an equation or a constraint. In solving for a particular variable (i.e. the output variable), it may be possible to combine some of the constants appearing in the equation or constraint. Rather than expand the constant name and value files, a second type of constant list entry has been invented. It contains only the forward link, the flag and an one or two word field reserved for the constant value. We shall differentiate the constants verbally by naming this

second type a local constant. The flag values for the equation value and local constant entries are 4 and 5 respectively. The flag value 3 is reserved to indicate which variable(s) is the output of a function, ER or constraint.

The connection of the basic GENDER building blocks into a network forms what is termed a group body. The group body is the possession of a node called a group. Generally, a group represents a collection of equations, ER's and constraints having a common trait. For instance, the members of a group body might all be participants in a cyclic calculation. A group node is formed of the usual network fields plus (t3f2, t4f3, t7f1-4, t8f1-4), of which it is the field (t7f1) that points to the group body.

The flag (t3f2) differentiates between a protected group (set flag) and an unprotected group (flag unset). The unprotected group may be modified by the analysis algorithms included in GENDER, whereas the protected group may not altered. An example of a protected group might be a completed solution procedure, perhaps retrieved from a solution procedure library, requiring no further analysis. The field (t4f3) appears in every GENDER list node and is provided as a programming convenience for GENIAO. The data fields (t7f2-4) and (t8, f1 and 4) are, in order, the pointer to the decision variable list, the pointer to the tear variable list, the depth, the pointer to the SIM and the method identifier. The pointers (t8f2) and (t8f3) are reserved for use with the dynamic programming algorithms to be added to GENDER at a future date. The entries of the tear and decision variable lists are identical to the entries on the output variable lists for functions, ER's and constraints, except that two words are reserved for each degree

of dimensionality. Each dimension requires two words so that a minimum and maximum to each index may be specified. This feature permits compactness with respect to dimensioned variables assigned as tear or decision variables.

* IV.4.d. GENIAO

The implementation of GENIAO was relatively straightforward, depending heavily on the COAST and NETPAC verbs. As was the case for SECIAO, GENIAO requires the reservation of seven words in the information block for data pertinent to the GENDER list. Table 15 lists these components with their respective contents.

The GIMBL is the GENDER information block, and is the analogy of SECBL for SECIAO. The first word of GIMBL points to the GENDER list. The address of the first GIMBL word is recorded in JCCORE(16). The second GIMBL word points to the SPUR block for list type 2. The SPUR block contains one five word SPUR for each possible list entry size from unity up to and including the largest possible GENDER list entry. The SPUR's are arranged in the block in ascending order. The third GIMBL word is reserved for the trace key applicable to the GENDER list at level 0. The remaining seven words of GIMBL contain the addresses of vectors employed during index calculations.

Each of the seven vectors is equal in length to the maximum possible dimensionality for a function, ER, constraint or variable. This integer is obtainable from the fifteenth word of the information block. Let us label the vectors A through G in the order they are referenced by GIMBL. The vectors A through G correspond exactly to the vectors a through g of Appendix B.

Although the GENDER list is principally a NETPAC implementation, REMOTE is employed by GENIAO. For both the input and output of a

TABLE 15

* Indices excluded

GENDER list, temporary storage is required for linkage data pertinent to the nodal connections. With rapid access being the paramount consideration, a file structure was selected for the temporary storage. Two files are employed, one for the current GENDER list level and one for the previous level. As the input of the current GENDER list level is completed, the files are interchanged so that the current level file now becomes the previous level file. Each file entry contains the address of a node and a pointer to an auxiliary list. The list entries each contain the file entry number of a predecessor node to the node labeled in the file entry.

CHAPTER V

ANALYSIS ALGORITHMS

The current selection of algorithms available with the GENDER System is somewhat limited. Though limited, the algorithms nevertheless do permit the development of a complete solution procedure according to a realistic analysis strategy. The selected strategy involves resolving cyclic calculations via minimum tear considerations.

Additional algorithms can be relatively easily provided. Several such additions are contemplated for GENDER in the near future. These additions are futher discussed in the concluding remarks of Chapter IX.

The rationale for the selection of algorithms for inclusion in GENDER depended upon two principal criteria. First, the algorithm must be of obvious utility with respect to solution procedure development generally. Secondly, the algorithm should be as simple as possible. This latter criterion arises since the algorithm must currently serve as a test and evaluation vehicle for the support and administrative facilities of the GENDER System.

The next three sections of this chapter describe the analysis algorithms selected to perform out put set assignment, precedence ordering and minimum tear selection. Rather than reproduce in this work the algorithms stepwise, reference will be made to the literature source of the algorithm version implemented. To be described in the following sections, then will be the essential characteristics of the algorithms as pertaining to the design engineer and to GENDER. The literature

references may be regarded as * flagged sections.

V.1. Hungarian Output Assignment Algorithm

The Hungarian algorithm for output assignment selected for GENDER is the version presented by Gupta (1972) in his master's thesis. To each variable in each equation, ER and constraint a cost or weight of selecting the variable as the output must be assigned. The selection of weights will, in general, reflect the design strategy.

The design engineer may simply assign equal weights to all variable/equation incidences. By so doing, he has reduced the Hungarian algorithm to an arbitrary output assignment procedure. This strategy minimizes the effort expended by the design engineer in obtaining an output assignment.

A second weight selection criterion, closely allied to the proceeding one, is user preference. The design engineer may wish to influence the Hungarian algorithm to make certain output assignments while avoiding certain other assignments. Thus, he would ascribe low weights to preferred assignments and high weights to undesired assignments. Although the weight range may be as large as desired the range 0-9 is envisioned to provide sufficient resolution to convey user preference.

Although a design engineer may weight each variable/equation incidence according to preference, it is more likely that a specific weighting scheme would be applied. For example, Lee and Ozawa (1971) and Soylemez and Seider (1972) suggest weighting on the basis of the algebraic complexity of solving for a variable in the event of selection as the output. While this increases the effort expended by the engineer, a more efficient solution procedure will likely result.

A final scheme for weight selection involves the determination of the sensitivities of each variable/equation incidence. If the weight is assigned as the negative of the logarithm of the sensitivity, than the Hungarian algorithm, which seeks to minimize the sum of the weights for a complete output assignment, will be performing output set assignment according to the maximum product criterion (Edie and Westerberg, 1971). This criterion has been shown to lead to rapidly convergent solution procedures to cyclic equation sets.

Chapter VII is a brief user's manual and discusses the use of the Hungarian algorithm. The subprogram performing this algorithm is designated HASSAL. As is the case for all of the analysis algorithms, the passed parameters required by HASSAL are minimal, being only the address of a group and a unique call statement identification number. The latter is an essential feature of the debug facilities incorporated into COAST and described via comments in Appendix A.

HASSAL operates on a single group, although this group may have groups as nodes on its group body. The effect of HASSAL on a group is the substitution of a new output assignment for the previous output assignment. The previous output set may, of course, be null. Unassigned variables at the conclusion of output assignment become decision variables and are recorded in the group.

V.2. Speed-Up Precedence Ordering Algorithm

The Speed-Up algorithm for precedence ordering is the product of research by Sargent and Westerberg (1964). Two algorithms are presented in the reference, but only algorithm I has been selected for use with GENDER. The subprogram name is SPEDUP.

SPEDUP performs precedence ordering of a group body on which the output set assignment is recorded. Only the address of a GENDER group and a call statement identification number are required as passed parameters by SPEDUP. The use of SPEDUP in an analysis strategy is discussed in Chapter VII.

The effect of SPEDUP is the reorganization of a group body to reflect precedence ordering. If the group body possesses an unresolved cyclic character, SPEDUP will create a new group containing only the equations which are not acyclic. That is, the cyclic equations are transferred from the original group body to the group body of a new group which becomes a member of the group body to the original group. The original group is, therefore, acyclic at the conclusion of SPEDUP. The sub-group into which the cyclic character has been concentrated may now be subjected to tear variable selection.

V.3. Barkley - Motard Minimum Tear Algorithm

The Barkley and Motard (1972) minimum tear algorithm was presented in a paper at the NATO Advanced Study Institute on Decomposition as a tool for solving large problems held in Cambridge, England. The program executing the Barkley - Motard algorithm is the subroutine BEMOAN.

BEMOAN requires the same passed parameters as HASSAL and SPEDUP. The GENDER group on which BEMOAN is to operate must posses an output set assignment. After selection of the tear variables has been made, the selections are recorded in the group. The deletion from consideration of the tear variables in all functions except where they are the output variables renders the group body acyclic. This strategy and the program SPEDUP are combined to precedence order the group body as the final BEMOAN step.

V.4. Implementation Details

Each of the analysis algorithms depends upon the existence of a sparse incidence matrix for the group under analysis. The concept of the SIM and the SIM manipulation verbs of SIMPAC were developed expressly for the implementation of analysis algorithms. Although the SIM is not always the appropriate medium for the execution of an algorithm, it is the most convenient medium for conveying to an algorithm the pertinent data relative to a group body.

An important feature shared by the analysis algorithms, and indeed by most of the major GENDER programs, is the high degree of subroutinization. While the delegation of tasks among subprograms can be carried to the extreme, a certain degree of task delegation greatly simplifies the debugging operation and enhances the readability of the code. HASSAL, SPEDUP and BEMOAN are hardly more that supervisor programs directing the operation and interaction of their respective subroutine sets.

In addition to the SIM, each of the analysis algorithms expects the existence of certain conditions before execution is attempted. For example, BEMOAN requires an output assignment before it can proceed. To save the design engineer from at least a portion of the details of solution procedure generation; each of the three analysis programs automatically generates missing information before proceeding. A subprogram DFAULT is employed to provide this service and is more fully described in Chapter VII.

Continuing the pattern established in previous chapters, the following section provide the implementation details and are generally only of value to readers contemplating modifications to existing programs or expansion of the analysis algorithm repertoire. Before attempting the

next three sections, it is strongly advised that familiarization with the Hungarian, Speed-Up and Barkley - Motard algorithms be acquired. Only the adaptation of the algorithms to the data structures available with GENDER will be discussed in the ensuing sections.

* V.4.a. HASSAL

HASSAL is by far the largest and most complex of the three analysis algorithms. Gupta (1972) presents the Hungarian algorithm in the form of two interactive algorithms. One of the algorithms resembles a supervisor directing the utilization of the other algorithm. It is essentially after this supervising algorithm that the program HASSAL is patterned. The steps of the algorithm for performing the output set assignment are parcelled among several subprograms.

The major subprograms employed by HASSAL consist of J2ACYC, J2AOSA, J2PATH, J2MARK and J2SWIT. The subprogram J2ACYC is the acyclic output assignment phase of the algorithm (steps 1 through 4 of Cruptas algorithm). Step 5 represents a decision and transfer of control step exterior to the domains of J2ACYC and of the next algorithmic phase, J2AOSA. Such control steps have been incorporated into HASSAL. Steps 6 through 8 constitute the instructions incorporated within J2AOSA. J2AOSA performs an arbitrary output set assignment. The remaining subprograms under the guidance of HASSAL expand the arbitrary output assignment into a complete assignment. A complete assignment is characterized by output variables assigned to every equation. Not all variables need be assigned; those remaining unassigned become decision variables.

J2PATH and J2MARK are both involved in the search for alternative output assignments which will permit the extension of the output set.

J2PATH performs steps 10 through 14 of the assignment algorithm. Alternative assignments are sought via a row and column marking scheme. Marking is also employed by steps 16 through 17, which are embodied in J2PATH. The marking strategy employed by J2PATH is some what more complex than that of J2MARK. Both programs result in the identification of Steward paths. J2SWIT is employed whenever a Steward path is identified to perform the output set adjustments. For paths discovered by J2MARK, J2SWIT must break one output assignment and make two new output assignments. For paths discovered by J2PATH, three output assignments are replaced by four new assignments. In either case, a gain of one assignment in the output set is noted.

HASSAL and its subprograms operate entirely on the sparse incidence matrix. A working ordinate is created for both the rows and columns. The working ordinate file entries are identical to the file entries of the primary ordinates. The principal function of the working ordinates is for the recoding of row and column marks. Marks are stored in data type 13, which is the data type employed by the primary ordinates for storage of output assignments. Thus, as a programming convenience, the SIM routine for output set assignment is employed for marking the working ordinates. No other temporary data structures are required for the implementation of the Hungarian algorithm.

* V.4.b. SPEDUP

The Sargent and Westerberg (1964) Speed-Up I algorithm was by far the easiest and most natural to implement. The algorithm was developed expressly for list processing. The authors propose four list structures for use with the Speed-Up I algorithm. With a sparse incidence matrix available to SPEDUP, two of the four lists need not be generated.

List 1 is an unordered list of all equations, ER's and constraints. The row ordinate of the SIM is a file containing references to the functions, ER's and constraints which SPEDUP is to reorder. Consequently, the row ordinate is substituted for list 1.

The lists of type 2 are described in the paper as providing data on the linkages between the elements to be precedence ordered. A type 2 list must be provided for each element to be ordered. Let us consider an SIM row. Each SIM row contains an output variable (perhaps several outputs for an ER), one or more input variable and perhaps one or more decision variables. The input variables, by virtue of their not being either outputs in a particular row or decision variables, must each be assigned as outputs to other SIM rows. Thus, the SIM rows furnish the linkage data directly and eliminate the need for creation of the type 2 lists. Note the one to one correspondence between row ordinate file entries and SIM rows.

Lists 3 and 4 must be created by SPEDUP. List 4 is employed as temporary storage during execution of the algorithm, with the final precedence ordering appearing on list 3. The algorithm stipulates the transfer of entries from list 4 to list 3 making it necessary to design only a single list entry data format serving both lists 3 and 4. The data format selected was (t1fl, t2fl, t3fl, t21fl, t22fl), with the list being GENDER type 2. Tables 16 and 17 are provided as a guide to the structure and contents of the entries on lists 3 and 4. Data types 1 and 2 serve as the forward and backward links as is usual with forward - backward lists. Data type 3 is a flag serving to differentiate equations (0) from decision variables (1) and groupings of equations (2). The contents of data types 21 and 22 depends upon the flag value.

TABLE 16

Data Fields for SPEDUP Working Lists

Data Type	LEND	Use Number	Use
1	V,V,V,V	1	Forward link
2	V,V,V,V	1	Backward link
3	V,V,V,1+	1	Flag (0 equation, ER or constraint, 1 decision variable, 2 grouping of equations, ER's and constraints)
21	V,V,V,V	1	SIM row number (flag = 0)
		2	SIM column number (flag = 1)
		3	Address of a list of grouping members (flag = 2)
22	V,V,V,V	1	Address of an SIM row element (flag =0)
		2	Address of a grouping member (flag = 2)
		3	Wasted

TABLE 17

List Entries on SPEDUP Working Lists

List Entry	Composition	Use
1	t1fl,t2fl,t3fl,t21flult22flul	Equation, ER or constraint
2	t1fl,t2fl,t3fl,t21flu2t22flu3	Decision variable
3	t1fl,t2fl,t3fl,t21flus,t22flu2	Grouping

If the value of the flag is zero, the list entry represents an equation, ER or constraint. In this situation, data type 21 contains the SIM row number and data type 22 contains the address of a row element. In particular, data type 22 refers to the next input of an equation, ER or constraint to be considered by SPEDUP. Data type 22 will initally point to the first element of the row.

If the value of the flag is two, the list entry represents a grouping of equations, ER's and constraints. Such groupings indicate cyclic information flow patterns among the group members. Data type 21 contains the pointer to a list of grouping members. The list entries on this auxiliary list are each identical to the list 3/4 entry with the flag set to 0. Data type 22 is also a pointer to an entry on the auxiliary list, but not necessarily pointing to the leading entry as is the case for data type 21. Data type 22 points to the first member of the grouping having a non-null input list. This pointer is advanced to the next grouping member when, during SPEDUP execution, the input list of a grouping member is depleted.

A flag value of 1 indicates the list entry to be representative of a decision variable. In this case, only data type 21 contains meaningful data. Data type 21 contains the SIM column number of the decision variable. Data type 22 is ignored.

The implementation of the Speed-Up I algorithm does not exhibit the degree of decentralization observed for HASSAL. This is principally due to the design of the algorithm. The majority of the steps are simple; that is, they do not contain instructions to perform complex or extensive manipulations. Further, the overall manipulations demanded by Speed-Up I are much less complex than those required for HASSAL.

* V.4.c. BEMOAN

BEMOAN is the supervisor program for the Barkley and Motard (1972) minimum tear algorithm. The algorithm employs precursor and interval lists to search initially for self-loops, then for two-way edges in an effort to reduce to null the set of interval lists. Nullity of the interval list set indicates complete elimination of the cyclic character in a group body by virtue of tear variable selections.

Instead of employing separate lists as suggested in the algorithm, the BEMOAN inplementation incorporates the list information into a single column ordinate. This working ordinate is composed of file entries containing the data fields (t3fl, t4fl, tl4fl). The LEND summary for these data fields is given by Table 18. The field (tl4fl) is a flag whose possible settings of 0, 1 and 2 respectively indicate the file entry to represent the head of an interval, an interval member and a tear variable. Note that the head of an interval is also a precursor either to itself or to another interval. The field (t3fl) contains the column number of the interval to which a variable belongs. This field is only of significance for a flag of 1. The field (t4fl) is used variously for counting membership of intervals in two-way edges or occurrences in other intervals. The number of occurrences of an interval in the other intervals is useful in selecting a tear variable when neither a self-loop nor a two-way edge is present. If the flag value is 2, both (t3fl) and (t4fl) contain no significant data.

TABLE 18

Data Fields for the BEMOAN Working Ordinate

Data Type	LEND	Use
3	1,V,V,V	SIM column number (the interval to which a variable belongs)
4	V,V,V,V	A working data field for temporary storage (used primarily as an accumulator)
14	V,V,V,V	Flag (0 variable is head of an interval, 1 variable is an interval member, 2 variable is a tear variable)

CHAPTER VI

INTERPRETATION

The GENDER list contains all of the instructions for solving an equation set. During the course of GENDER list development via the algorithms, no modifications are imposed upon the original equation set. The equation set stored in SECEDE serves only as a source of information. When a design engineer employs GENDER, the ultimate objective is, of course, the solution to the equation set and not merely the instructions for obtaining that solutions.

Two choices are apparent at this point. The engineer may impose the algebraic rearrangements and precedence ordering on the equation set as per the GENDER list instructions. He may then program, for instance in FORTRAN, the evaluation of the output variables, including the resolution of cyclic calculations. It is possible to provide a FORTRAN converter as an integral component of the GENDER system.

While FORTRAN conversion of the GENDER list could have been provided, it was rejected for the present version because of the difficulty in performing modifications to the FORTRAN source module. Changes to the source module might originate from reanalysis of a cyclic group if convergence problems are encountered, or they might originate from alterations in the active constraint set during constrained optimization. Even assuming that the modification of FORTRAN code could be conveniently accomplished, re-compilation would remain a necessity.

The foregoing considerations led to the examination and ultimate

selection of an interpreter system. By interpretation we mean execution directly from the GENDER list. The interpretation of a GENDER list is a three step process; link edit, convert and interpret. The link edit step creates for each equation, ER and constraint a list of components with variable value storage locations explicitly addressed. The conversion step performs any required algebraic manipulations on the link editor generated lists.

The following sections describe the interpretation capability designed for GENDER. Since the advantages of interpretation will not be fully realized until the advent of a constrained optimization supervisor for GENDER, and since the creation of this supervisor is somewhat distant, the interpretation capability has not been fully implemented. To ensure compatability with the currently implemented GENDER components, the essential features of interpretation have been carefully analyzed. The remainder of this chapter reflects the results of this analysis. The inclusion of this information in a description of GENDER has been prompted by two factors. (1) It will form the basis for the implementation of the interpreter, and (2) the interpreter (coupled with the notion of constrained optimization) provides an insight into the justification for the implementation of GENDER as a complex, list processing-based system.

VI.1. Link Editor

At the completion of analysis, the GENDER list contains all of the instructions necessary to solve an equation set. However, the GENDER list contains only the instructions, for the equation set is stored in SECEDE. As files in SECEDE, the equation set is virtually unavailable with respect to performing the modifications recorded on the GENDER list - i.e. algebraic rearrangements. Therefore, it is necessary to generate

a second copy of the equation set in a form amenable to modification.

The link editor, LINKED, provides each group body entry with a linked list of the constituents in the equation, ER or constraint represented by the group body entry. Thus, the second copy of the equation set is distributed over the entire GENDER list. This distribution has the characteristic of automatically conforming to the precedence ordering exhibited in the GENDER list.

Now let us consider a variable appearing on a link editor list (LEL). In terms of interpretation, the really important aspect of the variable is not its code name, but is its value storage location. Since the variable value files are integrated into SECEDE, the use of REMOTE verbs is necessary to determine value storage addresses. While it is of no consequence for acyclic groups, deferring address determinations until interpretation causes the address of a variable to be determined on every iteration during convergence of a cyclic group. Consequently, each LEL entry representing a variable value is provided by the link editor with the address of the variable value storage location.

VI.2. Converter

The converter, COVERT, has three primary duties: (1) solve LEL's algebraically for the output variable, (2) install equation, ER and constraint evaluation list entries into LEL's, and (3) provide a method insert to the group bodies of cyclic groups. The converter is programmed to accomplish all three tasks with only a single trace through the GENDER list.

A method is a subroutine required to direct the successive selection of tear variable values as a means of accelerating the convergence of cyclic groups. Methods are identified in the GENDER system by the method code. This code is recorded in the data field (t8f4) of each group. A

code of unity indicates a group to be acyclic, while a code of zero indicates that a group has not yet been subjected to the analysis algorithms. Thus, the reference by the method code to actual methods begins with the code 2.

All cyclic groups, that is all groups having a method code of 2 or larger, must have a method insert as the last accessible node of the group body. The order of access is, of course, dictated by the verb NEXT. The contents and structure of the method insert has already been presented in Tables 13 and 14 in Chapter V. The purpose of the method is twofold: (1) to indicate to the interpreter that repitition of the group body is required and (2) to provide information required by the method subprogram.

In general, a method subprogram requires a vector of values for evaluated equations, ER's and constraints, and a vector of tear variable values. The evaluated entities and the tear variables will be equal in number. The objective of the method subprogram is the selection of tear variable values which drive the values of the evaluated entities as close to zero as practicable. Since some convergence accelerators, i.e. methods, rely on a history of tear variable and evaluation values over several iterations, this data is provided as an auxiliary to the method insert.

The current or latest values for both variables and evaluated entities are provided as a linked list containing the addresses of storage values. That is, these lists are essentially LEL's. The old values for both tear variables and evaluated equations, ER's and constraints are provided via an application of REMOTE. A single catalogue references two records. The first record contains a single file of tear variable values. Each file entry contains all of the old values for a particular tear variable. Therefore, if the last 5 values (excluding the current

value) are required, then each file entry will accomodate 5 value fields. To avoid unnecessary shifting of the contents of a file entry when a current value becomes the most recent old value, an indexing scheme is proposed. An index is stored in the method insert which indicates which of the old values is the most recent. For example, an index of 2 indicates the values in the second value field of each file entry to be the most recent. By subtracting unity (modulo 5) one determines the value field to receive the current value just prior to the creation of a new set of current values. The twenty-second word of the information block (whose address is JCCORE(17)) contains the number of old values to retain. The second record, identical to the first, is reserved for the values of evaluated equations, ER's and constraints.

The second of the three functions performed by COVERT involves the addition of evaluation list entries to the LEL's of equations, ER's or constraints. In particular, such modification is performed on entities declaring a tear variable as the output. Further, this modification is only performed if the method code stipulated in the group node is greater than five. The method codes two through five are special cases in which the tear variables are calculated as output variables. Thus, for codes two through five, the method subroutine must rely only on the current tear variable values and perhaps a history of old tear variable values to provide an estimate of the tear variable values for the next iteration.

The first of the three COVERT duties enumerated in the first paragraph of this section requires the capability of algebraically manipulating an LEL. All of the LEL manipulative power has been concentrated in a general algebraic package, GALAP. This program package has

been developed expressly for the GENDER system as an independent research effort. The listings for GALAP have been included in Appendix A. User interface with GALAP is via the programs SOLVE and MATH. SOLVE permits the algebraic solution of an equation or constraint for its output, while MATH determines the value of an output variable based on the current value of the input variables to an equation or constraint. As one might suspect, it is SOLVE which is employed by COVERT.

VI.2.a. SOLVE

The program SOLVE is employed to solve algebraically for a particular variable. The variable of interest is indicated to SOLVE by the occurrence of a flag value 3 for an output variable or a flag value 4 for an evaluation entry. The evaluation entry is viewed by SOLVE to be identical to an output variable. SOLVE accomplishes the algebraic rearrangement by initially expanding the LEL into a network structure. The algebraic rearrangement is actually performed on the network, which is collapsed back into an LEL after the algebraic manipulations have been completed.

Algebraically speaking, SOLVE is not always capable of solving an equation or constraint for its incident variable. If purely algebraic manipulations cannot solve an equation for a particular output variable, then SOLVE must fail. For example, algebraic manipulations alone cannot reduce the equation

$$x + y = \ln X$$

to the form

$$x = f(y)$$

SOLVE is, however, empowered to recognize and perform many simplifications. For example, the equation

$$x + y = 2x$$

becomes

$$x = -y$$

if x is designated as the output variable. Further, the equation

$$2(x + 2) - y = 9$$

becomes

$$x = y/2 + 2.5$$

again with x as the output variable. In order to accomplish the combination of constants, the constant entries on the LEL are released and new constants introduced. The new constants are termed local constants. That is, they are constants appearing only in one equation, with each equation having its own set of local constants.

Table 19 indicates the operators which SOLVE is capable of recognizing and manipulating.

VI.3. Interpreter

Put quite simply, the task of the interpreter is the determination of the values for all variables except the decision variables. However, the size and complexity of the interpreter program GLINT indicates the presence of some latent complexity in this simple task.

With respect to acyclic groups, the assignment of values to output variables is relatively simple. Each equation, ER and constraint constituting an acyclic group need be considered once only. The GALAP program MATH is employed by GLINT to effect all output variable evaluations for solved equations and constraints. The presence of an ER on an acyclic group body somewhat complicates the procedure since the calling of the subprogram (i.e. ER) is necessary. The procedure for calling subprograms is the subject of section VI.3.b.

The necessity of calling method subprograms further complicates

TABLE 19

Operator Set

Unary		Binary		Other	
Symbol	Code	Symbol	Code	Symbol	Code
COMP	1	=	101	+n	201
SIN	2	-	102	*n	202

SQUARE	12				

the resolution of cyclic groups, which by their cyclic character automatically require the repetitive evaluation of all concomitant output variables. The aspect of repetition requires that data be saved which will permit the reinitiation of the calculations at the beginning of a group body should satisfaction of the convergence criterion fail at the termination of an iteration. The program METHOD, discussed in section VI.3.b, is responsible for evaluating a group with respect to the convergence criterion, unless such a comparison is performed by the method subroutine.

If the interpreter encounters an error condition, the interpreter will return to the calling program the address of the group under consideration and a code indicative of the particular error. Table 20 lists the error codes which the interpreter is designed to recognize. The executive program prepared by the design engineer must be programmed to follow a recovery procedure for each error code.

VI.3.a. MATH

Like SOLVE, MATH is constrained to equations and constraints constructed with the operator set tabulated in Table 19 of section VI.2.a. MATH exists in two versions; one for single precision floating point arithmetic and one for double precision floating point arithmetic. The design engineer must select the MATH version appropriate to the accuracy demanded for the design computations. Since all variables must be either single or double precision, election to employ double precision may cause a significant increase in memory requirements. In view of the numbers of other machine instructions required to support the interpretation process, selection of double precision should not affect execution times.

VI.3.b. Subroutines

The subroutines which the interpreter GLINT must call are ER's and

TABLE 20

GLINT Error Codes

Error Code	Condition
1	Zero method code
2	Missing output assignment
3	Link editor list missing
4	No LEL entry flagged as output
5	LEL syntax error
6	Tear variable list missing for cyclic group
7	Method insert missing for cyclic group
8	Convergence excessively slow

methods. The design engineer must provide the programs EXTRA (for ER's) and METHOD (for methods). Essentially, each of these programs is a library of call statements for the various ER or method subroutines. The ER and method code names are employed to access the appropriate call statement via a computed GO TO statement. Note that for an ER, two computed GO TO's must be employed: one conditioned on the unit number and a second conditioned on the ER code name exlusive of the unit number modifier.

This procedure for calling subroutines during GENDER list interpretation may seem somewhat crude. However, in light of the original decision to remain machine independent to the largest possible extent, the use of the call statement libraries EXTRA and METHOD is inescapable.

In addition to the library functions of EXTRA and METHOD, these programs must also perform transformations on the data to be provided to an ER or method. That is to say, most ER and method subroutines accept values as data rather than the addresses of values so prevalent in GENDER list interpretation. The value address of interest to EXTRA are distributed within the LEL's of the ER's. The ER output variables will be indicated by LEL entry flags equal to 3 just as for the output of an equation or constraint. For METHOD, the value addresses are available from an LEL-type list and an old value file. One list/file pair will be available for both the tear variables and the evaluated entities (equations, ER's and constraints).

Since it is the duty of METHOD to employ a method subroutine for the purpose of returning to GLINT a new set of tear variable values from which new values for the evaluated entities are to be determined, METHOD must update the old value storage files. The nature of the update procedure is suggested in section VI.2. Finally, METHOD must be programmed

to test for convergence when employing any method subroutine into which a convergence test has not been incorporated. Typically, a convergence test would involve the comparison of the latest tear variable value with its predecessor as for example in a sum of the squares of the differences technique. METHOD indicates satisfaction of a convergence test by returning zero to GLINT in substitution for the address of the method insert.

VI.4. Implementation Details

In the subsections to follow, we shall concentrate on the implementation details for LINKED, COVERT and GLINT. As per the pattern established for previous chapters, these sections are marked with an * and may be omitted by all readers not requiring this detailed data.

The information of the ensuing subsections is not necessary to the preparation of the programs EXTRA and METHOD. Sections VI.2 and VI.3.b provides, when used in concert with Tables 13 and 14, sufficient information on the data structures involved. The user must thoroughly understand the LEL, method insert and old value storage structures. The programming tools are provided principally by COAST and REMOTE. In accessing LEL entries for an ER, LNKFWD and FRMCEL should be used to effect the advance and data transfer operations rather than POPUP. Although POPUP does perform the advance and data transfer operations automatically, POPUP also destroys the list as it proceeds. Remember that for cyclic groups or in the event of group reanalysis, the LEL's will be utilized repetitively.

* VI.4.a. LINKED

LINKED is basically a supervisor program for the link editing step. NEXT is employed to access the group body entries of either a single group or an entire GENDER list. LINKED utilizes the group body flag

(t3fl) to identify the particular group body constituents, each of which is treated separately.

A group on a group body causes no action by LINKED save to access the body of the group via NEXT. Equations, ER's and constraints all carry group body flags of 2. All entries with flags of 2 are referred to the IOPAC program JlLEDL for LEL generation. The flag value 3 is reserved for method inserts. The LEL-type list entries, as well as the old value storage files, are released via CORN for later reallocation. The field (tl6fl) is the address of the SPUR employed with CORN.

* VI.4.b. COVERT

COVERT, like LINKED, is primarily a supervisor program. Also like LINKED, COVERT employs NEXT to access the group bodies. For the group body entries representing equations and constraints, COVERT utilizes SOLVE to solve algebraically for the output variable. The output variable list of each group body indicates which of the LEL entries are to recieve flags of 3. Although SOLVE is not generally employed for ER's, the flagging of the output variables on the LEL is performed.

An exception to the exclusion of ER's from algebraic rearrangement is the declaration of an ER to be an evaluated ER. Equations, ER's and constraints become evaluated entities when the method code is greater than 5 and when an output variable is also a tear variable. COVERT makes a direct comparison of each output variable list encountered to the tear variable list for all groups having method codes exceeding 5. An evaluated entity receives an additional LEL entry with a flag of 4. This entry represents the value of the evaluated entity. COVERT requisitions a storage location for the value. The convention for including the new LEL entry is (1) place the new entry at the end of

the LEL and (2) add to the new end of the LEL a list entry representing the equal operator. To understand this procedure, we must first recall that the equations and constraints stored in SECEDE conform to the reverse polish notation with the "= 0" implied. Since the LEL's are developed from SECEDE, it follows that the LEL's will also be in reverse polish without the "= 0" actually appearing. Let us now consider the conversion of an equation

$$f(x,y,z)$$

(written in reverse polish notation) to an evaluated equation. Including the evaluation entry and the subtraction operator, the equation becomes

$$f(x,y,z)F =$$

or in standard notation

$$F = f(x,y,z)$$

COVERT is programmed to release an evaluation entry discovered on LEL prior to the output variable list/tear variable list comparison. the elimination of an evaluation entry is simplified by the use of reverse polish notation for the LEL and by the fact that evaluation entries are encountered only as the algebraic output of the LEL. Thus, an evaluation entry may always be deleted by removing from the LEL the last two list entries; the evaluation entry and the equality operator. The storage location assigned to the evaluation entry is placed on the available space for later reallocation.

For groups possessing method codes greater than 1, COVERT must install a method insert as the last accessible node on the group body. The end of the group body is indicated by a change in level following a call to NEXT. COVERT retains the address of the last node to effect the access to the last group body node once a level decrease is noted.

COUPLE attaches the method insert to the last group body entry. COVERT establishes the value storage lists and files discussed previously in sections VI.2 and VI.3.b. The tear variable list furnishes the data required for establishment of the storage facilities necessary for the tear variables. No such list being automatically available, COVERT develops the LEL-type list for evaluated entities as the evaluation entries and the value storage locations are created. Note that this list will not be created for method codes less than 6. The storage facilities of NEXT are employed to store the address of a partially completed list of evaluation entries whenever a level increase occurs - i.e. whenever a group is encountered on the group body of another group.

* VI.4.c. GLINT

GLINT uses NEXT to trace through either a single group or an entire GENDER list performing numerical evaluations with MATH and EXTRA. At the conclusion of each group possessing a method code exceeding unity, GLINT must call METHOD. If METHOD returns the address of the method insert, iteration on the current group body is necessary. Conversely, if METHOD returns zero for the address of the method insert, the convergence criterion has been satisfied and consideration of the next group may begin.

To facilitate the iteration on group bodies, GLINT uses a temporary list to store the address of the group. If an interior group is encountered, a new entry is pushed onto the temporary list. The trace of a group body is repeated by first incrementing the group trace key (t4f2) by unity. The trace is begun directly with the first group body entry rather than with the group. This procedure is essential to preserve the temporary lists upon which NEXT depends.

A program called NUMBER serves as an interface between GLINT and MATH. NUMBER directs MATH in the computation of an output variable value. NUMBER maintains a push-down list for the storage of operands (variables and partial results) in the fashion of a stack. NUMBER begins with the first LEL entry in computing an output value. Each operand encountered is stored on the push-down list until an operator is encountered. The encounter of an operator causes NUMBER to pop-up from the push-down list (PDL) a number of operands equal to the order of the operator (t2lfl). MATH performs the operation of the operator on the selected operands, and the result is placed on the PDL. The computation is complete when both the LEL and the PDL are simultaneously exhausted.

CHAPTER VII

USER MANUAL

In this chapter we shall not try to present all of instructions for using the GENDER System. Rather, we shall discuss briefly the essential instructions on a somewhat superficial level. References to text and tables in other chapters will furnish the details. The intent is the creation of a guide to the use of GENDER while repeating information already presented to the smallest extent possible.

Two principal areas of activity are required of the design engineer prior to employing GENDER: (1) preparation of input data and (2) program preparation. Each of these very general instructions contain a number of steps and are discussed in the sections to follow.

One instruction which fits in both the data preparation and the program preparation areas is the preparation of the information block. The data required to establish the information block may be input either via a READ statement or via a DATA statement.

VII.1. Input Data Preparation

The input data may be categorized as follows: (1) the core allocation, list and data field information required by COIN, (2) the information block, (3) SECEDE and (4) an initial GENDER list. Category 4 is optional and would be supplied when the continuation of a previous problem analysis is desired. The data in categories 1, 3 and 4 are input via the programs COIN, SECIAO and GENIAO respectively. The data formats for each of these programs are presented in the comment statements for the respective programs in Appendix A.

The data required to initialize the core allocation and list processing package read by COIN furnishes the means by which a design engineer may tailor GENDER to the machine available. If performed with caution and foresight, the preparation of the data for COIN may need be performed only once for a given machine environment. Tables 2, 3, 5, 6, 9 and 13 give the LEND's required for the various list types. The table entries indicated by a V represent variables which the engineer is permitted to choose. Perhaps we should review the definition of a LEND. For example let us consider a data field occupying bit positions 4 through 7 of the second and third words of a list entry. The four LEND components are, in order, the word index of the first field, the word index of the last field, the shift and the mask. For the data type we are considering, the LEND would be (2, 3, 2^3=8, 2^4-1=15). The aforementioned tables must be used in conjunction with Tables 10 and 14 for determining the data organization within the list and file entries. It is the data organization adopted by the engineer which will assign integer values to the V's in the LEND tables.

Table 21 lists all of the components to the information block. In general, numerical values can be assigned to each of these components only after the data for COIN has been prepared. Since the information block is to be established by the user provided main program, the format for the information block data is a matter of user preference.

VII.2. Program Preparation

Program preparation involves the coding of three programs by the design engineer. The programs METHOD and EXTRA are described in Chapter VI. Note that even if no ER's have been included in the problem, a program named EXTRA must still be provided to avoid an unresolved external reference error.

TABLE 21

Information Block

Component	Use	Component	Use
1	Length of a record segment	15	Highest possible dimensionality
2	Length of a floating point value	16	Ordinate segment size
3	Length of an alphameric name	17	Length of horizontal/vertical link pair
4	Length of a scalar variable file entry	18	Length of an element list entry
5	Length of a constant file entry	19	Length of an ordinate file entry
6	Number of segments requested	20	Length of a GALAP diverger
7	Unit scale factor for code names	21	Length of a GALAP node
8	Length of a diverger list entry	22	Reserved
9	Length of a group node	23	Reserved
10	Length of a group body node	24	Reserved
11	Length of an output list entry	25	Reserved
12	Length of a variable LEL entry	26	Number of old values to retain
13	Reserved	27	Maximum number of iterations
14	Length of insert for method	28	Convergence criterion

The third program which must be supplied by the user is a main program which must be supplied by the user is a main program. This program is the executive routine which will supervise the data input operations, problem analysis and solution, and the output of results.

The data input operations might be regarded as an initialization phase prior to attempting to solve the problem. In this phase, the program COIN is called, the information block is established and the program SECIAO is called. If the input of a GENDER list is desired, GENIAO is employed. Note the order of events for the initialization phase, for successful initialization is possible only in this order. Establishment of the information block involves the acquisition, via NEWCEL, of a list entry at least 22 words long. The data may be read directly into this list entry. Finally, the storage of the address of the list entry in JCCORE(17) completes the procedure.

The remainder of the main program is devoted to the analysis and output phases. The analysis strategy is limited to weighted output assignment and then minimum tear for the present. The future expansion of ALPAC (or perhaps additions to ALPAC by the design engineer) will permit alternate strategies. The completed solution procedure (i.e. - GENDER list may be output via GENIAO. SECEDE may also be output using SECIAO. To facilitate the resumption of analysis at a future date, punched output of both the GENDER list and SECEDE from GENIAO and SECIAO is available. If direct interpretation of the GENDER list is elected, either VARIAO or SECIAO may be employed to obtain the numerical results of the calculations. Note that the main program must be coded to react properly to any contingencies which may develop during interpretation. This topic of error recovery has already been discussed in Chapter VI.

In the event a user may wish to employ output facilities other than those afforded by GENIAO, SECIAO or VARIAO, JCCORE (13) must be set equal to 6 prior to the utilization of any GENDER program. JCCORE (13) serves as a printer carriage control character. The integer 6 indicates that a new line is to be begun for the next output. This internal carriage control does not supercede formated carriage control instructions, but applies only to GENDER - generated trace and error messages.

VII.3. Additional Algorithms

It was noted in the preceeding section that the algorithm selection currently available permits only a single analysis strategy. While it is planned to expand the algorithm library in the near future, it is unlikely that it will be possible to satisfy the needs of all potential users. Thus, it is likely that a design engineer will wish to program an analysis algorithm himself.

Before attempting the expansion of the algorithm library, certain of the * marked sections must be read. In particular, the purpose of an analysis algorithm is to modify a GENDER list. Consequently, the * marked section pertaining to the GENDER list must be understood. If the algorithm to be implemented is to employ a sparse incidence matrix, and particularly if the matrix operations are not presently provided in SIMPAC, the implementation details or SIMPAC must be read. The * marked sections for all data structure manipulation packages must be regarded similarly to SIMPAC whenever the manipulations to be imposed on the data structure are not the standard manipulations provided in GENDER.

VII.4. GENDER as a Design Tool

The design of a chemical processing plant is a rather complex procedure. Let us consider the impact of GENDER on the single design phase concerned with the differentiation of processing alternatives.

In response to a proposed raw materials/products set, the design engineer will develop a number of possible processing schemes. By omitting processing elements such as pumps and heat exchangers a simplified flowsheet can be created. The simplified flowsheet should retain only those units essential to the intent of the processing scheme. From the simplified flowsheets, mathematical models maybe developed employing short cut and simplification techniques wherever possible. The equation sets thus developed may be subjected to analysis and interpretation via GENDER. The design engineer has been relieved of the burden of solving the several modes either by hand or by programming the models for computer solution.

Frequently, the resolution of the crude models is insufficient to distinguish the best processing scheme from one or two other proposals. Consequently, it may be necessary to perform a run-off comparison between a subset of the original possible schemes. This second level comparison can afford improved resolution only if the accuracy (and the complexity) of the remaining models is increased. If the re-comparison involves only a few models, the development of models describing the processes to the greatest possible extent may be justified. Again, GENDER is to be employed for solution procedure generation and interpretation.

The GENDER list of the model selected as best should be retained for conversion (by hand) to a FORTRAN program. This program should be found to be quite useful as a comparison to actual plant performance. The model may even be of utility in establishing set joints for automatic control.

It is realized that the use of GENDER as a design tool is limited by the lack of an optimization supervisor to the GENDER system. A

program package performing constrained optimization would lend a higher degree of credibility to the model comparisons, particularly for the higher resolution models. Futher, it would improve the steady state performance predictions required to select optimally controller set points.

CHAPTER VIII

EXAMPLES

In this chapter we shall consider the application of GENDER to two example problems; equilibrium flash and a simple binary distillation. The equation set describing the behavior of a binary equilibrium flash operation is not dissimilar to the equation set pertaining to a distillation equilibrium stage. Consequently, it is possible to propose a single equation set sufficing, with minor modifications, for both examples.

We shall adopt the convention that the tray numbers of a distillation column increase from bottom to top. The letter I will be employed to represent the tray number. Figure 13 illustrates the general distillation tray, for which the following equations have been prepared.

(1) $K_{I,1} X_{I,1} - Y_{I,1} = 0$

(2) $K_{I,2} X_{I,2} - Y_{I,2} = 0$

(3) $\left[\exp\left(\frac{-0.120}{T}(32000) - 2.30(7.6)\right)\right]/P - K_{I,1} = 0$

(4) $\left[\exp\left(\frac{-0.120}{T}(39000) + 2.30(8.3)\right)\right]/P - K_{I,2} = 0$

(5) $X_{I,1}L_I + Y_{I,1}V_I - Z_{I,1}F_I - X_{I+1,1}L_{I+1} - Y_{I-1,1}V_{I-1} = 0$

(6) $X_{I,2}L_I + Y_{I,2}V_I - Z_{I,2}F_I - X_{I+1} - Y_{I-1,2}V_{I-1} = 0$

(7) $L_I + V_I - F_I - L_{I+1} - V_{I-1} = 0$

(8) $Z_{I,1} + Z_{I,2} - 1 = 0$

(9) $X_{I,1} + X_{I,2} - 1 = 0$

(10) $h_{L,I}L_I + H_{V,I}V_I - h_{F,I}F_I - h_{L,I+1}L_{I+1} - H_{V,I-1}V_{I-1} - Q = 0$

(11) $H_{V,I} - h_{L,I} - 2 = 0$

(12) $H_{V,I} - H^{\circ}_{V1}(Y_{I,1}) - H^{\circ}_{V2}(1 - Y_{I,1}) - (\alpha_1 Y_{I,1} + \alpha_2(1-Y_{I,1}))T + (\beta_1 Y_{I,1} + \beta_2(1-Y_{I,1}))T^2 = 0$

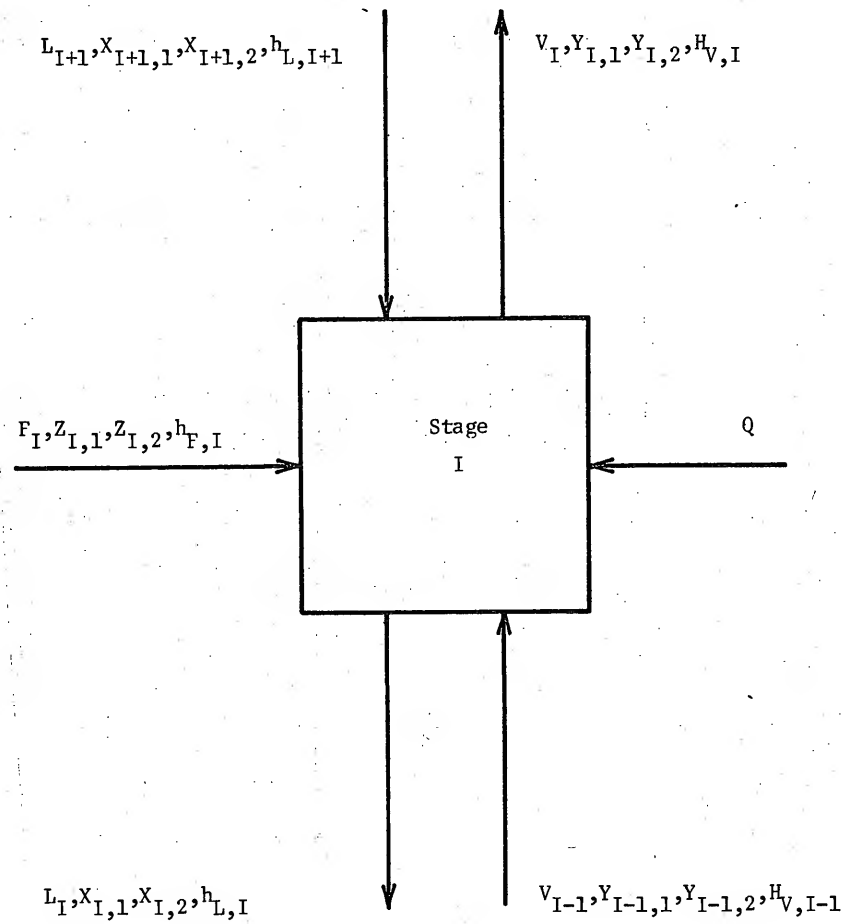

Figure 13 An Equilibrium Stage.

This equation set is adapted from the equations presented by Edie (1970) as an illustration of equilibrium flash. Two basic assumptions are implied by this equation set: (1) Raoult's law holds and (2) the pressure is constant throughout the column.

For both of the examples, the twelve equations will be regarded as a processing unit. The encoding of the equations for the creation of a unit in SECEDE requires the assignment of code names to each of the variables and constants. Table 22 presents the code name/variable assignments, while Table 23 provides the analagous information for constants.

To illustrate the preparation of the data required to establish the twelve equations describing a distillation tray as a unit in SECEDE, Figure 14 is provided. The formats for each of the input cards are given in the prefatory comment statements for the program SECIAO in Appendix A. With respect to the equation files, it must be recalled that the reverse Polish notation is employed. For example, equation 1 written in reverse Polish is

$$K_{I,1}X_{I,1} * Y_{I,1} - 0 =$$

Note that in the reverse Polish notation, all operators appear explicitly. GENDER has been programmed to "assure" the 0 = terms for equations in which an explicit equality is not declared. Thus, equation 1 is encoded for SECEDE as if it were simply

$$K_{I,1}X_{I,1} * Y_{I,1} -$$

In Figure 14, the cards terminating files contain messages indicating their specific function. This is in contradiction with the SECIAO requirement for concluding files with a blank card. The comments were included in Figure 14 for clarity and must not actually appear in the

Figure 14 (Continued)

data prepared for SECIAO.

VIII.1. A Simple Analysis Strategy

Both of the example problems share a common, simple analysis strategy. This strategy consists of the following steps:

1. Call HASSAL to perform output set assignment
2. Call SPEDUP to precedence order the acyclic equations and to collect the cyclic equations into groups
3. Call BEMOAN to select the tear variables for a cyclic group and to perform precedence ordering within a cyclic group
4. Repeat from step 2 if any cyclic groups remain unanalyzed

The analysis strategy is implemented in the main program prepared by the user.

In addition to the analysis strategy, the main program must also perform the administrative duties of preparing memory for allocation (via COIN), creating the information block and creating SECEDE (via SECIAO). The data required by COIN is contained in Figure 15. The LEND's selected for these example problems specify all data fields, except those for the seven part indices, to be whole words each. The example problems are sufficiently small to make memory conservation tactics unnecessary for the IBM-370/165. The whole word data items have the distinct advantage of rendering an allocatable core map (i.e. JCCORE) readable. The values of the information block components reflect the use of whole word data fields. These values are presented in Table 24.

VIII.2. Equilibrium Flash

An equilibrium flash is essentially a distillation tray for which the L_{I+1} and V_{I-1} are both zero. This situation is depicted in Figure 16. There are at least two acceptible ways of adapting the 12 equations

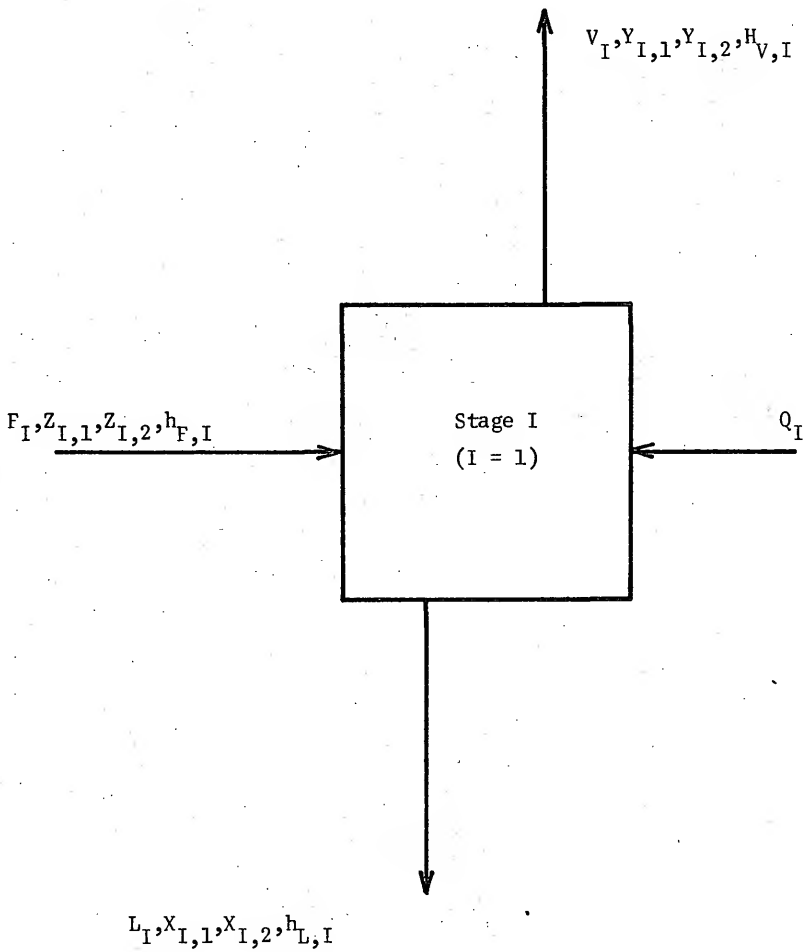

Figure 16 Equilibrium Flash.

describing a distillation tray to the equilibrium flash problem.

One method is suggested by the nature of the data required by SECIAO for establishing SECEDE. Each constituent of an equation (whether it be a variable, an operator or a constant) appears on a separate card. That is to say, an equation is constructed in SECEDE by supplying SECIAO with an ordered sequence of cards, each of which represents a component of the equation. Consequently, it is possible to remove cards to effect the elimination of the variables pertaining to the (I+1) and (I-1) stages. Care must be exercised in editing the equation, set by the simple expedient of removing cards, to avoid the introduction of syntac errors by failing to eliminate the variables associated with the eliminated variables.

Aside from the physical editing of the equation set, another alternative is available. If the variables pertaining to stages I+1 and I-1 could somehow be declared to be decision variables, and if the values of L_{I+1} and V_{I-1} could somehow be declared to be zero, then the transformation of the distillation tray equation set into the equilibrium flash equation set would be accomplished. If it is desired, the decision variable file and the variable value file supplied as data to SECIAO may be ammended to achieve the above declarations. This procedure, as was the case for the method of the preceding paragraph, entails the alteration of the SECIAO data.

If the alteration of the SECIAO data is to be avoided, while still accomplishing the task of declaring the variables L_{I+1} and V_{I-1} to be decisions valued at zero, recourse to a small amount of programming will be necessary. The program VARIAO must be employed to set the values for L_{I+1} and V_{I-1} at zero. This task may be installed in the main program at any point prior to interpretation (or any other use for variable

values, such as sensitivity analysis). It is suggested that VARIAO precede the use of LINKED.

The task of declaring the I+1 and I-1 stage variables to be decisions must be completed prior to initiation of equation set analysis. In other words, the declaration must precede the use of HASSAL. Although programs whose names begin with J are not normally recommended for direct user call, the program J2TADV may be employed to obtain decision variable list entries for the variables of stages I+1 and I-1. These entries, when linked together and installed on the group decision variable list, establish the variables of stages I+1 and I-1 as decision variables. The modification of the decision variable list is best accomplished immediately after geneation of the crude GENDER list by CUDGEL.

If J2TADV and VARIAO are to be employed to effect the tailoring of the distillation tray equations to equilibrium flash, the input data for SECEDE is shown in Figure 17. The symbol TRAY represents the inclusion of the unit data contained in Figure 14. The data required by VARIAO is presented in Figure 18. Should the reader desire to run this problem, using the data from Figures 14, 17 and 18, a comparison of the results obtained may be made with Appendix C. The machine listing presented in Appendix C was created from the GENIAO card output. Since this card output is consistent with the input format expected by GENIAO, the input format described in the prefatory comment cards for GENIAO (Appendix A) should be employed as the key for deciphering Appendix C.

The declaration of decision variables without revising the SECIAO data may be extended to other decision variables. For example, the elimination of the I+1 and I-1 stage variables leaves 16 variables in a

```

Figure 18 Data for VARIAO

problem involving only 12 equations. Obviously, four of the remaining variables must be decisions. The inclusion of the four decision variables on the decision variable list follows exactly the procedure for the I+1 and I-1 stage variables. However, unlike L_{I+1} and V_{I-1}, the values for the decision variables supplied to VARIAO via data will in general be unequal to zero.

Edie (1970) selected $Y_{I,1}$, P_I, V_I and F_I to be the four decision variables reducing the problem to a 12 variable/12 equation problem. Note that the user selection of decision variables is not necessary. HASSAL effects decision variable selection by regarding as decisions all variables remaining unassigned at the conclusion of the Hungarian algorithm. Weighting the variable/equation incidences can force HASSAL to select $Y_{I,1}$, P_I, V_I and F_I to be the decisions. In fact, the output assignments selected by Edie (1970) can be duplicated by HASSAL with the proper weights (based on the maximum product criteria).

In retrospect, the key feature presented in this section have been (1) the modification of a general problem formulation to a specific problem and (2) a procedure for the declaration of user selected decision variables, with particular emphasis on procedures for effecting the necessary alterations without recourse to revisions of the SECIAO data. Great importance has been placed on general problem formulations and maintaining the integrity of SECIAO data primarily because the preparation and modification of SECIAO data are tedious operations. A library of general formulations for common processing units prepared as SECIAO data should prove invaluable to the design engineer.

VIII.3. Binary Distillation

Figure 19 depicts a three tray distillation column employing a reboiler and a total condenser. The trays have been diagrammed separately

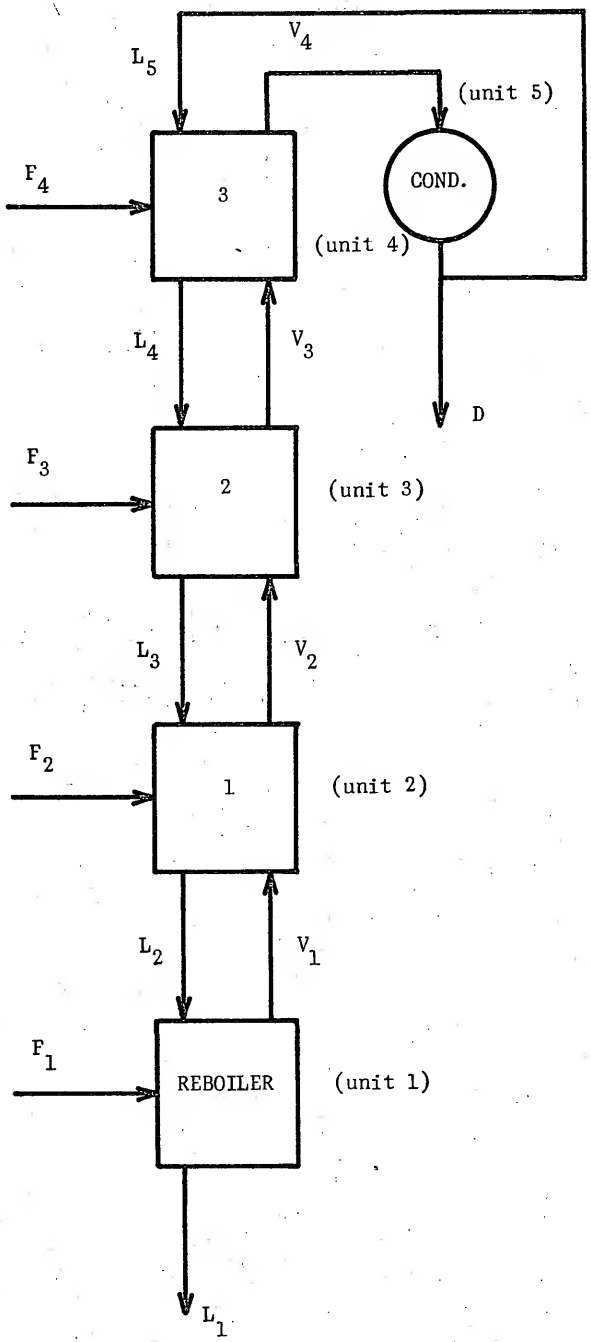

Figure 19 Simple Distillation Column.

giving the column a disjointed representation. This has been done to emphasize the designation of each tray as a separate unit. The primary purpose of this example is to illustrate the SECEDE provisions for assembling a collection of units into a processing scheme.

Units 1 through 4 are designated as the reboiler and the three trays respectively. Unit 5 represents the partitioning of the overhead vapor into a product and a recycle stream. The equations associated with total condensation are

(13) $X_{I,1} - Y_{I-1} = 0$

(14) $X_{I,1} + X_{I,2} - 1 = 0$

(15) $L_I + D - V_{I-1} = 0$

(16) $L_1/D - R = 0$

(17) $H_{V,I-1} V_{I-1} - H_{L,I} V_{I-1} - Q = 0$

(18) $H_{V,I-1} - H_{L,I} - 2 = 0$

The variables R and D represent the recycle ratio and the distillate product flow rate.

Two steps are required to declare commonality between variables of several units. First, a common variable value storage location must be reserved in unit 0. This is accomplished with the variable declaration file for unit 0. Second, the code name of the unit 0 variable must be installed in the declaration file entry for each of the unit variables for which commonality is to be established. The second step is accomplished via the variable declaration files for the affected units.

The use of the variable declaration files to provide the connections between processing units is illustrated by Figure 20. Figure 20 is the SECIAO data required to establish SECEDE for the three tray distillation column. The variable declaration file appears explicitly in Figure 20 for all units. The remaining files for units 1 through 4

Figure 20 (Continued)

are indicated by the symbol TRAY. These files for units 1 through 4 are identical to the files presented in Figure 14. Note that unit represents the reboiler, for which the V_{I-1}, Y_{I-1} and H_{I-1} variables are meaningless. These variables should be eliminated from consideration prior to the algorithmic analysis phase according to the instructions of the proceeding section.

As a specific example of commonality, let us consider the variable L_2. This particular variable appears in both units 1 and 2. Let us assign the code name 1 to the unit 0 variable we shall employ for the variable L_2. An inspection of the variable declaration file for unit 1 reveals a common variable declaration of 1 for the variable L_{I+1}. Similarly, the variable L_I for unit 2 also carries 1 as the common variable declaration. Consequently, L_{I+1} for I = 1 and L_I for I = 2 share a common value location (with the code name 1) in unit 0.

Should the reader wish to run this problem, the fully analyzed GENDER list may be compared with the machine listing in Appendix D. The SECIAO data for the distillation problem may be extracted from Figures 14 and 20. It is recommended that a single copy of the Figure 14 data be prepared and tested with SECIAO. Once the bugs, if any, have been removed, this card deck should be employed as the master for generating the three additional copies required on a duplicating card punch. When collated with the data prepared from Figure 20, the unit data decks will be integrated into a processing problem. Appendix D, following the example of Appendix C, is the machine listing generated from the GENIAO card output.

CHAPTER IX

CONCLUSION

The GENDER System has been developed to assist the design engineer with large scale design problems. This initial version of GENDER, however, is not completely suitable for a production system. Modifications and additions to GENDER have already been planned (1) to improve convenience aspects and (2) to include additional analysis algorithms.

IX.1. Convenience Aspects

Let us consider the contact of the design engineer with GENDER. To employ GENDER, an engineer must encode the equation set in the format expected by SECIAO. Further, the output of SECEDE via SECIAO produces code. Similar considerations apply to GENIAO and the GENDER list. The coded input/output is a usable medium for communication with GENDER, but is not a convenient medium. GENDER would be simpler to use, if the input/output language was already familiar to the design engineer. The adaptation of algebraic equations for the input/output medium is contemplated, perhaps ultimately resembling the input/output language developed by Soylemez (1971).

Another aspect of the engineer/GENDER interface involves the user prepared main program. In the current version of GENDER, a main program directs the solution procedure development. This program must be devised to properly react to error conditions recognized as a consequence of analysis or perhaps even interpretation. It is most probable that many of the preconceived error conditions would never be realized for a particular design problem. Thus, the effort of developing a complex error

recovery mechanism is somewhat wasted. So far we have been describing the utilization of GENDER in the batch mode. Let us now consider a real time interactive environment. The responsibility for creating the main program would be relieved from the user entirely. Instead the user would employ a console to direct GENDER in performing an analysis strategy. The user need not consider alternative strategies until an error condition has been detected. If a recovery procedure cannot be immediately conceived, the user may temporarily leave the system after employing GENIAO and SECIAO to output the GENDER list and SECEDE. Analysis may be resumed whenever a corrective course of action has been charted. Further, the interactive environment facilitates monitoring either the development or the interpretation of a solution procedure at the discretion of the user.

Optimization is an essential factor in design. GENDER has been developed to permit convenient constrained optimization. For the present, the search for optimality has been left to the user. The development of an optimization supervisor to the GENDER System has been proposed. The theoretical foundation for the optimization program has already been established by DeBrosse (1971). The existence of this program should relieve the design engineer of a considerable burden.

IX.2. Additional Algorithms

In Chapter VII, we noted that the algorithms provided with GENDER allow only a single analysis strategy. Albeit a realistic strategy, one cannot expect it to suffice in all instances. Several algorithms have been proposed for inclusion in the analysis repertoire.

In section V.1. it was pointed out that the weights employed by HASSAL in performing output set assignment could be derrived from a sensitivity analysis. The resulting output set assignment would thus be rapidly

convergent (Edie and Westerberg, 1971).

The use of HASSAL to obtain output set assignments enhancing the convergence of a solution procedure is expected to be relatively simple to implement. However, there is an inherent disadvantage. HASSAL makes no attempt to differentiate between the convergence properties of every output set assignment. An algorithm developed by Edie (1970), based on the creation of a dynamic programming network, selects the best output set from the standpoint of convergence and singularity of the resulting Jacobian. Once implemented, this algorithm should be regarded as something of a last resort since the extensive network manipulations are expected to entail high execution times.

The influence of the output set assignment extends beyond the convergence properties of a solution procedure. For a particular design problem, the output set determines the minimum number of tear variables. The criterion for output set assignment may be arbitrary weights, user preference or sensitivities. Let us consider minimum tear as the criterion for output set selection. With this criterion, the output set selected would be the set for which the minimum number of tear variables would be the minimum over all possible output sets. The adaptation of this criterion to an algorithm performing both output set and minimum tear selections has been accomplished by Christensen (1970). As in all cases where an improvement in the results of an optimization is expected, the Christensen algorithm is more complex than BEMOAN. In fact, it is vastly more complex. Consequently, a user must cautiously weigh the advantages of perhaps reducing the number of tear variables against the increased execution time over BEMOAN.

The algorithms discussed in the proceeding paragraphs already exist in the literature, there remaining only the adaptation to GENDER. Another

algorithm currently being devised focuses on the compaction of GENDER lists via indexing considerations. These considerations parallel the simplification of FORTRAN programs by employing DO statements. As one might suspect, pattern recognition plays a key role in the identification of indexed GENDER list components in a repeating sequence. Considerable simplification to the GENDER list and to the SIM's is anticipated for all staged and discretized unit processes, such as distillation and absorption.

IX.3. A Final Note on GENDER

The current version of GENDER is heavily diagnostic. That is, many more tests, with provisions for diagnostic messages, are performed than are essential to the task of solution procedure manipulation. These tests must be removed before GENDER can begin to assume the configuration of a production system. The tests were originally devised as debugging conveniences. However, by retaining the myriad tests, GENDER affords the research engineer with a convenient medium for developing and testing analysis algorithms, and for studying the influence of analysis strategies on solution procedures.

C                              **********
C
C       PURPOSE
C           SPEDUP PERFORMS THE SARGENT AND WESTERBERG SPEED-UP I
C           ALGORITHM.
C
C       USAGE
C           CALL SPEDUP(JCGRUP,JCMODE,JCCLNO)
C
C       DATA FORMAT
C           N/A
C
C       USAGE
C           JCMODE = 0 OR 1 AS RESPECTIVELY THE SIM IS OR IS NOT TO BE
C                    RELEASED AT THE CONCLUSION OF SPEDUP
C           SEE HASSAL FOR ALL OTHER PASSED PARAMETERS.
C
C       REMARKS
C           THE NUMBER REPRESENTED BY JCTCIA MUST, FOR SOME MACHINES,
C           REPLACE THE 1 IN THE NAMED COMMON STATEMENT.
C           SPEDUP UTILIZES CUDGEL, SIMGEN AND HASSAL TO AUTOMATICALLY
C           PROVIDE ANY LIST STRUCTURE OR FEATURE REQUIRED FOR THE
C           SPEED-UP I ALGORITHM.

C
C       SPECIAL INSTRUCTIONS/LEND
C           THE FIRST DATA TYPE MUST HAVE A LEND OF (1,0,1,0).  THE
C           SECOND DATA TYPE MUST HAVE A LEND OF (2,0,1,0).  THE THIRD
C           AND FOURTH DATA TYPES INDICATE THE NUMBER OF FILE ENTRIES
C           AND THE NUMBER OF WORDS PER FILE ENTRY RESPECTIVELY.  THE
C           LEND FOR THE THIRD DATA TYPE MUST HAVE 1 AS THE SMALLER
C           WORD INDEX.  THE FOURTH DATA TYPE MUST HAVE AS THE LARGER
C           WORD INDEX OF ITS LEND THE NUMBER OF WORDS IN THE PRE-FILE
C           PARAMETER SET.
C
C       SPECIAL INSTRUCTIONS/DEBUG
C           THE FOLLOWING INDICATES THE ORDER FOR OPERATIONAL CHECKS
C           OF THE REMOTE SYSTEM.  THE PROGRAMS OF LEVEL THREE, FOR
C           INSTANCE, CALL ONLY SUBPROGRAMS FROM LEVELS ONE AND TWO.
C           SIMILARLY FOR ALL OTHER LEVELS.
C               SUBPROGRAM          LEVEL          PROGRAM ID. NUMBER
C               SUPPLY              0              4
C               C4STUP              1              10
C               C4ADR1              2              6
C               C4ADR3              3              8
C               C4NEXT              3              9
C               C4AOR2              4              7
C               C4ADRS              5              5
C               C4TRAN              6              11
C               FETCH               7              1
C               FIND                7              2
C               STORE               7              3
C
C       SPECIAL INSTRUCTIONS/COAST
C           REMOTE MUST BE SUPPORTED BY THE COAST SYSTEM, AS REMOTE IS
C           ESSENTIALLY A LIST STRUCTURE COMPOSED OF LIST ENTRIES WHICH
C           ARE EQUAL TO OR LARGER THAN A CORE SEGMENT.  THE CATALOGUE
C           AND REGISTER SEGMENTS ARE EQUAL IN SIZE TO A CORE SEGMENT.
C           THE SIZE OF THE RECORD SEGMENTS IS SPECIFIED BY JCSPUR(4).
C           THE LIST TYPE INDICATED BY JCSPUR(5) MUST BE FORWARD-
C           BACKWARD.
C
C       SPECIAL INSTRUCTIONS/OFF-LINE STORAGE
C           ONLY RECORD SEGMENTS MAY RESIDE ON OFF-LINE STORAGE.  THE
C           RECORD SEGMENT ADDRESS CONTAINED IN THE REGISTER WILL BE
C           NEGATIVE FOR ALL RECORD SEGMENTS ON OFF-LINE STORAGE.  THE
C           ABSOLUTE VALUE OF THESE NEGATIVE INTEGERS MAY BE UTILIZED
C           AS AN AIDE TO INFORMATION RETRIEVAL.  FOR THE PROGRAM
C           SUPPLY, A PROGRAM MUST BE SUBSTITUTED TO PERFORM THE
C           RETRIEVAL OPERATION IF OFF-LINE STORAGE IS TO BE EMPLOYED.
C           SUPPLY IS THE ONLY MACHINE DEPENDENT ROUTINE WITHIN REMOTE.
C           JCSPUR(4) SHOULD BE SET EQUAL TO THE RECORD LENGTH IN WORDS
C           FOR THE OFF-LINE STORAGE DEVICE UTILIZED.  THE CORE SEGMENT
C           SIZE AND JCSPUR(4) NEED NOT BE EQUAL, BUT JCSPUR(4) MUST
C           NOT BE LARGER THAN THE LARGEST ALLOWED CORE BUDDY.

C                          **********
C                          * C4AORS *
C                          **********
C
C       PURPOSE
C           C4AORS COMPUTES THE ABSOLUTE ADDRESS OF A FILE ENTRY
C           SPECIFIED BY A LISTER VECTOR.  C4AORS ALSO COMPUTES THE
C           MODEL AND LOESS VECTORS.
C
C       USAGE
C           CALL C4AORS(JCSPUR,LISTER,LOCAL,LOESS,MODEL,IODINE,JCFINE,
C           JCLOAD,JCSORF,JCCLNO)
C
C       DATA FORMAT
C           N/A
C
C       DESCRIPTION OF PARAMETERS
C           JCSPUR = A VECTOR CONTAINING THE POINTER TO THE USER,S CORE
C                    ASSIGNMENT MASK, THE POINTER TO THE USER'S
C                    AVAILABLE SPACE LIST HEADCELL, THE NUMBER OF
C                    SEGMENTS REQUESTED, THE NUMBER OF WORDS PER
C                    SEGMENT, AND LASTLY THE INDEX SPECIFYING THE LIST
C                    TYPE.  THE JCSPUR VECTOR MUST CONTAIN THESE FIVE
C                    ENTRIES IN THE INDICATED ORDER.
C           LISTER = AN N DIMENSIONAL VECTOR SUCH THAT, LISTER(1)=N,
C                    LISTER(2) IS THE RECORD NUMBER.  THE NEXT N-3
C                    WORDS OF LISTER CONTAIN THE INTEGERS FOR DIRECTORY
C                    SELECTION.  LISTER(N) IS THE FILE ENTRY NUMBER.
C                    IF LISTER(N)=0, THE ADDRESS COMPUTED WILL BE THAT
C                    OF THE FIRST FILE WORD OF THE FILE SELECTED BY
C                    LISTER(N-1).  NO OTHER LISTER WORDS MAY BE ZERO.
C                    IF LISTER(1)=1, LISTER(2) CONTAINS THE NUMBER OF
C                    FILE ENTRIES FROM THE CURRENT ONE TO ADVANCE.  THE
C                    DIRECTION OF MOVEMENT IS INDICATED BY THE SIGN OF
C                    LISTER(2), + FOR FORWARD AND - FOR BACKWARD.
C           LOCAL  = A USER SUPPLIED VECTOR INDICATING THE DATA TYPES
C                    FOR TRANSFER.  THE FIRST WORD INDICATES THE NUMBER
C                    OF DIFFERENT DATA TYPES, AND IS FOLLOWED BY THAT
C                    NUMBER OF SETS OF THREE WORDS EACH.  THE FIRST OF
C                    A THREE WORD SET IS THE DATA TYPE NUMBER FOR THIS
C                    LIST TYPE, WHILE THE REMAINING TWO WORDS ARE
C                    INDICES INDICATING THE FIRST AND LAST OCCURRENCE
C                    OF THE DATA TYPE FOR TRANSFER.  IF THE THIRD WORD
C                    OF THE SET IS ZERO, THE LAST ITEM TRANSFERRED WILL
C                    BE THE LAST ITEM INDICATED IN THE LEND COMPONENT
C                    (DATA LOCATION ARRAY) FOR THE CURRENT DATA TYPE.
C                    IF LOCAL(1)=-1 NO DATA TRANSFER OCCURS, AND IF
C                    LOCAL(1)=0 ALL DATA IN THE FILE ENTRY IS
C                    TRANSFERRED.
C           LOESS  = A FOUR WORD VECTOR PATTERNED AFTER LOCAL.  LOESS
C                    CONTAINS THE INFORMATION SPECIFYING THE DATA ITEM
C                    FOR TRANSFER IN SUCCEEDING FILE ENTRY PARTITIONS.
C           MODEL  = A FOUR WORD VECTOR PATTERNED AFTER LOCAL.  MODEL
C                    APPLIES TO THE DATA ITEM FOR TRANSFER IN THE
C                    CURRENT FILE ENTRY PARTITION.
C           IODINE = A PARAMETER INDICATING THE THREE WORD SET IN LOCAL
C                    FROM WHICH LOESS AND MODEL ARE TO BE FORMED.
C           JCFINE = A VECTOR CONTAINING (LISTER(1)-1) COMPONENTS.  THE
C                    FIRST (LISTER(1)-3) WORDS CONTAIN THE NUMBER OF
C                    FILE ENTRIES IN THE RESPECTIVE (LISTER(1)-3)
```

```
C               DIRECTORIES.  THE LAST TWO WORDS OF JCFINE CONTAIN
C               RESPECTIVELY THE NUMBER OF FILE ENTRIES AND THE
C               NUMBER OF WORDS PER FILE ENTRY OF THE FILE
C               ULTIMATELY SELECTED BY LISTER.  THIS IS A USER
C               PROVIDED VECTOR, WHICH NEED CONTAIN MEANINGFUL
C               INFORMATION ONLY FOR THOSE DIRECTORIES AND FILES
C               WHICH HAVE NOT BEEN PREVIOUSLY ESTABLISHED.
C       JCLOAD = A THIRTY WORD VECTOR.  THE WORDS OF JCLOAD HAVE
C               THE FOLLOWING USAGE.
C                 1 = ADDRESS OF CATALOGUE OR REGISTER SEGMENT WORD
C                 2 = ADDRESS OF CATALOGUE OR REGISTER SEGMENT
C                 3 = SEQUENCE NUMBER OF CATALOGUE OR REGISTER
C                     SEGMENT
C                 4 = ENTRY NUMBER IN CATALOGUE OR REGISTER SEGMENT
C                 5 = ADDRESS OF RECORD SEGMENT WORD
C                 6 = ADDRESS OF RECORD  SEGMENT
C                 7 = WORD NUMBER IN RECORD SEGMENT
C                 8 = FILE ENTRY NUMBER
C                 9 = NUMBER OF FILE ENTRIES IN FILE
C                10 = NUMBER OF WORDS PER FILE ENTRY
C                11 = ADDRESS OF FIRST WORD OF FILE
C                12 = NUMBER OF FILE ENTRIES OR SEGMENTS TO ADVANCE
C                13 = VARIOUS
C                14 = + FOR DATA TRANSFER INTO A FILE ENTRY, AND
C                     - FOR DATA TRANSFER FROM A FILE ENTRY
C                15 = MODE INDICATOR
C                16 = FIRST WORD OF LOCAL FOR NUMBER OF FILE
C                     ENTRIES
C                20 = BASE ERROR CODE
C                21 = RELATIVE ADDRESS OF FIRST EMPTY WORD IN
C                     RECORD
C                22 = NUMBER OF WORDS IN PRE-FILE PARAMETER SET
C                23 = FIRST WORD OF LOCAL FOR NUMBER OF WORDS PER
C                     FILE ENTRY
C                27 = RELATIVE ADDRESS OF CURRENT FILE ENTRY
C                28 = ADDRESS OF FIRST RECORD WORD
C                29 = 0 FOR FILE ENTRY BOUNDARY ENFORCEMENT, AND -1
C                     FOR ALLOWED BOUNDARY VIOLATION
C                30 = ADDRESS OF POINTER TO FIRST CATALOGUE SEGMENT
C       JCSORF = SEE FETCH
C       JCCLNO = A USER ASSIGNED CALL STATEMENT ID. PARAMETER
C
C   REMARKS
C       THE NUMBER REPRESENTED BY JCTCIA MUST BE SUPPLIED IN THE
C       COMMON STATEMENT FOR SOME MACHINES.
C       IF JCLOAD HAS NOT BEEN INITIALIZED, JCLOAD(15) MUST BE SET
C       TO -1 BY THE USER PRIOR TO CALL FOR ANY REMOTE SUBROUTINE.
C       JCLOAD(29) MUST NOT EQUAL -1 UNLESS VIOLATION OF FILE ENTRY
C       BOUNDARIES IS TO BE PERMITTED.
C       THE FIRST RECORD WORD CONTAINS THE RELATIVE ADDRESS OF THE
C       FIRST EMPTY RECORD WORD.
C       THIS ROUTINE IS NOT INTENDED FOR DIRECT USER CALL.

C
C       SPECIAL INSTRUCTIONS/ERROR CODES
```

```
C
C          AN ERROR MESSAGE IS OF THE FOLLOWING FORM.
C              ERROR N ( , , , , ) E  D
C          WHERE EACH   INDICATES IN ORDER OF OCCURRENCE
C          1  THE NUMBER OF SUBROUTINES CURRENTLY ENTERED
C          2  THE SYSTEM ID. NUMBER
C          3  THE LEVEL ID. NUMBER
C          4  THE PACKAGE ID. NUMBER
C          5  THE PROGRAM ID. NUMBER
C          6  THE CALL NUMBER
C          7  THE ERROR CODE
C          8  THE DATA PROVIDED TO AID IN DETERMINING THE NATURE OR
C             CAUSE OF THE ERROR
C          FIELDS 2 THROUGH 6 UNIQUELY IDENTIFY A PROGRAM CALLING THE
C          SYSERR ROUTINE.  FIELDS 7 AND 8 ARE PASSED TO SYSERR.  A
C          NEGATIVE ERROR CODE INDICATES A FATAL ERROR, TERMINATING
C          EXECUTION.  EXECUTION CONTINUES FOR A POSITIVE ERROR CODE.
C          JCCORE(14) PROVIDES THE MEANS FOR OVER-RIDING THE SIGN OF
C          AN ERROR CODE.  WHEN SET AT ZERO, JCCORE(14) HAS NO EFFECT.
C          IF -1 IS THE VALUE OF JCCORE(14), THEN ANY ERROR COMMITTED
C          IS FATAL.  IF +1 IS THE VALUE, ANY ERROR WILL BE NON-FATAL.
C
C        SPECIAL INSTRUCTIONS/DUMP
C            IF A DUMP OF JCCORE IS DESIRED WHEN AN ERROR CONDITION IS
C            ENCOUNTERED, JCCORE(19) MUST BE SET EQUAL TO A NON-ZERO
C            INTEGER.  IF POSITIVE, ONLY PRINTED OUTPUT WILL BE
C            PROVIDED.  FOR BOTH PRINTED AND PUNCHED OUTPUT, JCCORE(19)
C            MUST BE SET TO -N, WHERE N IS THE DATA SET REFERENCE NUMBER
C            FOR THE CARD PUNCH.  JCCORE(19)=0 SUPPRESSES THE DUMP.
C
C        SPECIAL INSTRUCTIONS/LAND, LEOR, LOR
C            LAND, LEOR, AND LOR ARE RESPECTIVELY THE FUNCTION NAMES FOR
C            THE LOGICAL OPERATIONS 'AND', 'EXCLUSIVE OR', AND 'OR'.
C            THESE FUNCTIONS MUST BE PROVIDED IN OBJECT DECK FORM.  THE
C            CURRENTLY INSTALLED OBJECT DECK IS COMPATABLE WITH THE
C            FOLLOWING MACHINES.
C                IBM 360 H LEVEL
C                IBM 370
C            THE TWO ARGUMENTS REQUIRED BY EACH FUNCTION ARE PROVIDED AS
C            PASSED PARAMETERS.
C
C        SPECIAL INSTRUCTIONS/TRACE
C            THE CODING REQUIRED FOR TRACING THROUGH EACH CALLED
C            SUBPROGRAM IS PROVIDED.  THIS OPTION MAY BE INSTALLED OR
C            REMOVED BY REMOVING OR INSTALLING THE COMMENT C ON EACH OF
C            THE AFFECTED CARDS.  WHEN INSTALLED, THE TRACE IS
C            CONTROLLED BY JCCORE(20) AS FOLLOW.
C                JCCORE(20) = 0  NO TRACE
C                             N  TRACE MESSAGE FOR ALL SUBPROGRAMS
C                                ENTERED UP TO THE POINT AT WHICH N
C                                SUBPROGRAMS ARE CURRENTLY ENTERED.  THE
C                                TRACE RESUMES UPON EXITING A SUFFICIENT
C                                NUMBER OF SUBPROGRAMS SO THAT THE
C                                NUMBER OF CURRENTLY ENTERED IS N OR
C                                LESS.
C            WHEN TURNING A TRACE OFF (BY SETTING JCCORE(20) TO 0), SET
C            JCCORE(13) TO 6.

C           JCMASK = THE MASK CORRESPONDING TO A DATA TYPE
C
C       REMARKS
C           THE NUMBER REPRESENTED BY JCTCIA MUST BE SUPPLIED IN THE
C           COMMON STATEMENT.
C           SYNONYMOUS TERMS FOR  DATA SET REFERENCE NUMBER  ARE
C            SYMBOLIC UNIT REFERENCE NUMBER,   SYMBOLIC UNIT NUMBER,
C            LOGICAL UNIT,  AND  LOGICAL FILE.
C           THERE WILL BE ONE DATA CARD FOR EACH DATA TYPE FOR EACH
C           LIST TYPE.  THAT IS, THE CARD SUPPLYING JCNODI MUST BE
C           FOLLOWED IMMEDIATELY BY JCNODI CARDS DESCRIBING THE DATA
C           TYPES.  ALSO THERE MUST BE JCNOLT SETS OF CARDS DESCRIBING
C           THE LIST TYPES.  THE FIRST AND SECOND DATA TYPES OF EACH
C           LIST TYPE MUST BE RESPECTIVELY THE FORWARD LINK AND IF
C           APPLICABLE THE BACKWARD LINK.

APPENDIX B

In its current version, there is no incentive for employing indexed variables and equations with GENDER. However, this will no always be the case. Memory and CPU time savings offer a strong incentive for the solution of such problems as pattern recognition. Since research is currently pursuing the index related problems, it was felt that ample justification existed for the inclusion of software within GENDER to provide an indexing capability.

The indices permitted in both SECEDE and the GENDER list are each composed of seven components. The components are data types 9 through 15 for both list types 1 (SECEDE) and 2 (GENDER list). The LEND's must be devised to permit the storage of all seven components in a single word.

The incentive for the complexity of the seven part index is a mechanism we shall call mapping. Mapping will in turn facilitate the implementation of the GENDER equivalent of FORTRAN DO loops. Let us consider an index i and an index j. Index i maps to index j if i is a function j - i.e. i = F(j). Thus, an output variable index may be a mapping of an equation index. If the equation index is permitted a range of values, the variation of the output variable index (as a consequence of mapping) will be automatic.

Index ranges in GENDER are permitted by the inclusion of a minimum index and a maximum index. Index ranges are allowed for equations, ER's, constraints and groups. This feature is expected to be of considerable

importance in reducing the analysis effort and storage requirements for multistage processing units.

For the purpose of considering the combination of the seven components into a single index value, let us identify the data fields 9 through 15 by the letters a through g respectively. Components a and b identify the index to be employed in the mapping calculation. When a is 1, b is the depth of the group supplying the index. Depth specifies the particular group in a cascade of dimensioned groups. When a is 2, b specifies the particular equation, ER or constraint index to be used. Indices are numbered in the order of appearance in the group body. When a is 3, b refers to an index of the same entity for which the index calculation is to be performed. That is, an equation index may be a function of another index of the same equation.

Using a and b, a mapping index j is selected. This j is related to i by the relationship.

```
i = j*(-1)**d*(e**(-1)**c) + (-1)**f*g
```

in which the FORTRAN operator symbols are employed. When use of a mapping index is not desired, the components a through f will all be valued at zero. To illustrate the use of this relationship, let us consider a numberical example. Suppose that we have a dimensioned output variable, one index, i, of which is one larger than the second function index, j. The seven components for the output variable index would be (2, 2, 0, 0, 1, 0, 1), to yield

```
i = j + 1
```

Each group on a GENDER list is permitted one index. Two words are reserved for the group index and are employed to store the minimum and maximum index values in the seven part format. This feature imparts the character of a DO statement to the dimensioned group. Since groups

are permitted on the group bodies of other groups, a cascade of DO loops can be simulated on a GENDER list. The group indices are numbered for identification in the order of encounter in descending from the outermost group to the innermost group. This number is termed the depth of the group. Note that undimensioned groups encountered in descending from group to inner group do not contribute to the depth computation. Also note that index calculations stipulating a mapping onto a group index will employ the current value of the group index. Current values to group indices are stored in the vector provided by CUDGEL when creating the crude GENDER list.

We shall consider a particular group at depth 3, with a current index value k. Let us continue our numberical example by assuming that j is four less than one half the index k for the group at depth 3. In this case, the seven components would be (1, 3, 1, 0, 2, 1, 4), giving the relation

$$j = k/2 - 4$$

Finally, assuming that k does not map onto another group index, the seven components representing k would be (0, 0, 0, 0, 0, 0, k). If k is valued at 8, then the mappings stipulate values of 4 and 5 for j and i respectively.

BIOGRAPHICAL SKETCH

James Richard Cunningham was born on January 14, 1942, in Houston, Texas, to Carl D. and Annette E. Cunningham. He was graduated from Destrehan High School at Destrehan, Louisiana, in June, 1959. In June, 1963, he was awarded the Bachelor of Science degree in chemical engineering from Louisiana State University.

Following graduation from Louisiana State University, he accepted a position at Texaco, Inc., in the Domestic Producing Department (Gas). His duties at Texaco involved primarily the operations aspects of the Paradis, Louisiana, natural gas recycling facility. This employment was terminated in January, 1964 for induction into the United States Air Force. He served four years as an egress system specialist, attaining the final grade of SSGT prior to honorable discharge. After discharge, he was employed at the Shell Chemical Company plant in Norco, Louisiana, as a technologist. In addition to providing technical support to plant operations personnel, he developed a computer simulation program modeling a reaction-distillation unit in the steady state.

In September, 1968, he elected to pursue graduate study at the University of Florida. He received the degree of Master of Engineering in chemical engineering in June, 1970.

James Cunningham is married to the former Eleanor Gayle Kincaid of Nashville, Tennessee. They are the parents of one son, Sean Carl, in whom they are well pleased.

I certify that I have read this study and that in my opinion it conforms to acceptable standards of scholarly presentation and is fully adequate, in scope and quality, as a dissertation for the degree of Doctor of Philosophy.

Arthur W. Westerberg, Chairman
